Autopsy.—There was no external trace of injury. The membranes of the cord were healthy. The substance of the cord was contused opposite the fourth and fifth cervical vertebræ. On section, there was found ecchymosis of the posterior horns of gray matter on the left side, and of the adjacent part of the lateral and posterior columns. There were also limited spots of ecchymoses on the right side, one in the right posterior column, and one in the right anterior horn of gray matter. The gray substance generally was hyperæmic. On removing the spinal cord and membranes, nothing abnormal was discovered in the vertebræ until the posterior ligament had been dissected off, when it was seen that the body of the fourth was separated from that of the fifth, and the left articular process of the fourth had been chipped off. Dr. John A. Lidell, who reports this autopsy, comments on it as follows: "The essential features of this instructive case are as follows: 1. The cord substance was injured by concussion, and not by any displacement of the parts; 2. the injury was attended by a number of minute extravasations of blood (ecchymoses) in the gray substance; 3. there were anæsthesia and loss of motion in both lower extremities and in the left arm; 4. there was paralysis of the sphincter ani and sphincter vesicæ, which denoted that the reflex motor apparatus was also paralyzed; 5. the anæsthesia passed away in the course of some hours, the return of sensibility being noted first in the parts most distant from the injury; 6. hyperæsthesia appeared synchronously with the reaction from 'shock,' and steadily increased in severity; 7. hyperæmia of the gray substance was found as well as ecchymosis. It should be remarked that the hyperæsthesia was more severe in the right arm than elsewhere, and this part had not at any time been paralyzed." This case was reported by Dr. Lidell as a pure or uncomplicated one of spinal concussion, but I am compelled to question the correctness of the report in this particular, and direct attention to the ruptured ligament, which it seems to me may have permitted a partial dislocation to have taken place—with contusion of the cord—the vertebræ afterwards having been restored to their proper position by the natural resiliency of the parts. The symptoms of paralysis were certainly more marked than they are usually in cases of pure, uncomplicated concussion of the spinal cord. The following microscopical report conveys a very clear idea of the pathological lesions observed in our experiments on animals in the cerebro-spinal axis when there were no complications in this centre.³ "Brain intensely hyperæmic otherwise normal. Every portion of the cord intensely hyperæmic. There were

punctate hæmorrhages in the dorsal and cervical regions of the spinal cord, in both the anterior and posterior horns, also in the middle commissure." The striking analogy existing between the pathological lesions in cases of death caused by electricity and the other cases of concussion, may be probably better illustrated by giving a condensation of the report of the autopsy made by Dr. Carlos F. McDonald on the body of William Kemmler, after execution by electricity, since this examination has been more carefully detailed than any of the others. The others, however, entirely agree with McDonald's so far as given. McDonald's report is as follows: "Rigor mortis marked. On incising the skin over the sternum, the blood which escaped was unusually dark and fluid, remained so on exposure. Lungs: tardieu spots were noticed on the posterior border of the lower lobe of the left lung, so also in the middle lobe of the right lung. Heart: valves and substance normal, ventricles empty. Liver: blood from cut surface of dark crimson hue. Gall bladder: distended with bile. Spleen: normal. Kidneys: both markedly congested. Brain: *capillary hæmorrhages* were noted in the floor of the fourth ventricle, also in the third ventricle and the anterior portion of the lateral ventricle. The perivascular spaces seemed to be distended with serum and blood." Dr. Spizka's report of the preliminary microscopical examination is as follows: "The brain, spinal cord and peripheral nerves appeared strictly healthy in every part examined, except in the area corresponding to the discolored (anæmic through the contraction of the vascular channels) area of the Rolandic and pre-Rolandic regions, the ventricular surfaces, the pons and the medulla oblongata. The latter, which had been the seat of post-mortem preservation of temperature approaching that of the normal human body, were distinctly softer than the observer has ever been accustomed to find these parts in autopsies on persons of Kemmler's age and performed so soon after death. The hæmorrhagic spots in the fourth ventricle, which were strongly marked, were not accompanied by signs of parenchymatous rupture of large blood vessels. Hence they may be regarded as having the same significance as the "taches de tardieu" found on the surfaces of the organs, notably the heart and lungs. The peculiar softened vesicular zone of tissue underlying the outermost layer of the cerebral cortex is noteworthy, as "the destruction line" runs parallel to the free surface of the brain and does not dip with the sulci. Examination of the fresh specimen revealed the existence of vacuoles (probably gas bubbles) in the ganglion cells and in the parenchyma of the "destruction line." From the fact that no hæmorrhages had occurred in this softened area it is a just inference that it was produced after life had become entirely extinct, for the continuance of a

³ An Experimental Study of Lesions arising from Severe Concussion, p. 22 et seq. by B. A. Watson, M.D., Philadelphia, Pa. P. Blakiston, Son & Co. 1890.

blood circulation in a softened brain area is incompatible with the bloodless appearance, already noted, and the absence of capillary hæmorrhages in this very district while they were present in those remote from the site of the electrode."

In order to approach the consideration of *malinger*, it is necessary to devote some attention to the traumatic conditions which frequently complicate concussion in the cerebro-spinal axis, since the majority of authors still include these morbid conditions under the head of "spinal concussion," "railway spine," etc. Fractures and dislocations of the vertebræ require little attention, at the present time, since they are easily diagnosed. The only exception to this rule will be found in those cases where there is a complete absence of deformity, which may be the case where the fracture consists in chipping off a portion of the articular vertebral surface, etc., or in an incomplete dislocation of a vertebra, in which the natural resiliency of the ligaments and muscles has restored the symmetry of the parts. In these cases, it is thought that the careful and observing surgeon will not be compelled to remain long in doubt as to whether the patient before him is a malingerer, or suffering from a real traumatic injury; since the prompt appearance of objective symptoms will certainly be largely dependent on the locality of the injury, while their degree of severity will depend very much upon the extent and character of the traumatism. There now remains for our consideration in connection with this subject, contusions, sprains, twists and wrenches of the back, which are entitled to a more thorough analysis than can be given them in this article, on account of their medico-legal bearings, in litigated cases. The study of these morbid conditions, it should be remembered, will be greatly simplified by bearing in mind the fact that their symptoms, the primary and secondary effects, are entirely analogous to injuries of the same character in other parts of the body. It is claimed that the spinal column and the bones which connect directly with it, are provided with ninety-nine articulations. The symptoms which characterize the morbid conditions now under consideration are pain, swelling, tenderness under pressure and occasional ecchymoses. The existence of the symptoms will be limited to the area involved in the traumatism, while the degree of severity will depend on the intensity of the injuries. There may be likewise, in some cases, constitutional disturbances which will aid in establishing the existence of a morbid condition. The ecchymoses and swelling are objective symptoms, and consequently entitled to due consideration, while the pain, stiffness and tenderness under pressure may require confirmation. The verification of the patient's statements on these points, and

frequently on others—especially questions involving the existence of paralysis—might be definitely put at rest by the proper use of an anæsthetic, which ought to be frequently employed in medico-legal cases. The general surgeon no longer hesitates to employ this agent in his private and public practice for diagnostic purposes, and why should it not be thus employed for the purpose of securing justice in our courts?

Drunkenness and syncope may make the diagnosis more difficult in certain cases of concussive accidents, whether it be pure or complicated concussion; but these factors are of short duration, and therefore cannot continue long to embarrass the surgeon. Having presented our views on the chief factors involved in the diagnosis of the so-called "railway spine," therefore we are prepared to devote a few minutes to the malingerer. It is unfortunately too frequently the case that a surgeon commences his examination, in medico-legal contests, after *having fully formed an opinion*, or at least a bias or prejudice. This, in many cases—in fact, almost universally—arises from the want of an analytical mind, and likewise the want of any carefully arranged system of examination. These are very serious defects in the expert witness and, when fully demonstrated, should disqualify him to give testimony. There is another serious defect, frequently observed in the members of our profession, which sometimes has its origin in laziness, although occasionally in an inordinate greed—where the physician has been *accustomed all his life* to give an opinion to a patient without either an examination or thought. It will be perceived that I have not yet reached the case of the malingerer; but I have thus far merely paid my respects to those who aid and assist the malingerer. The malingerer is certainly entitled to a careful and thorough examination, and each surgeon employed in the case ought to proceed in his examination with the same degree of care and caution that the most conscientious chemist would exercise, when required to make a chemical analysis in the interest of justice. It therefore becomes highly important to learn the true history of the litigant, and likewise that of his father, mother, brothers and sisters. All these matters have a special bearing on the case. It will be readily admitted that any person who has established a good character for truthfulness and honesty ought not to be classed with a mere adventurer. In the examination of all the factors involved in these cases of so-called "railway spines," the fact should never be lost sight of that *correct scientific opinions can only be reached by a systematic, methodical and painstaking investigation*.

Let us here present a brief *résumé* of some of the points which have been more or less considered in this paper.

1. The term concussion, as used by those who

first employed it, was erroneously defined, and unfortunately restricted in its application to the brain. These errors had their origin in a deficient knowledge of the pathological lesions engendered by concussive force.

2. Concussion is a more or less violent shaking or agitation of various organs in the body, producing functional derangements dependent on vaso motor changes and well-defined pathological lesions.

3. Concussion may be either general or special, general when several organs are involved at the same time, or special when the entire concussive force is expended on a single organ.

4. The symptoms arising from concussion will chiefly depend on the extent of the pathological lesions and the functions of the organs.

5. The frequency with which concussion will occur in any particular organ will depend on the point to which the concussive force is applied, the relative weight of the organ, the character of its texture, and the protection afforded by its anatomical surroundings.

6. The fifth statement supplies the explanation of the comparatively frequent occurrence of concussion of the brain, lungs, liver and kidneys to that of the spinal cord.

7. Concussion of the brain and spinal cord is always attended with immediate symptoms.

8. Concussion of the brain or spinal cord without immediate symptoms is a mere hypothesis—a myth—and has no real existence.

9. There is no pathognomonic symptom of concussion in any organ of the body; but a thorough, systematic, methodical examination by a skilled surgeon will secure a correct diagnosis.

Finally, I desire to reiterate the fifth conclusion expressed by Dr. Henry Hollingsworth Smith, in a paper which he read before the Surgical Section of the American Medical Association in 1889, which is as follows: "No physician should go into court and swear that a plaintiff has had a concussion of the spinal cord, or of its nerves, unless he has proved the disturbance of the normal functions of the cord, as shown in sensation or motion, or both, and that the symptoms appeared soon after the injury."

A CONSIDERATION OF TRAUMATIC LESIONS OF THE SPINE RESULTING FROM RAILROAD AND OTHER INJURIES—THEIR ETIOLOGY, PATHOLOGY AND DIAGNOSIS.

Read before the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY THOMAS H. MANLEY, A.M. M.D.,
VISITING SURGEON TO HARLEM HOSPITAL, NEW YORK.

Since the enormous extension of the railroad system—surface, submarine and elevated—wherein steam is utilized as a motor, the attention of surgeons and the profession has been attracted to certain special features, which commonly attend or subsequently follow accidents, sustained by individuals on cars in motion, on iron rails.

Many have maintained that injuries resulting from railway disasters, possess characteristic and positive lesions, which are peculiar to themselves, in symptomatology, pathology and termination. While, on the contrary, there are not a few, who take an opposite view and claim identity of analogy, between them and other disorganizations of tissue, in which the collision of heavy, moving bodies has been the direct cause, or in which similar physical agencies, but devoid of steam propulsion, have come into action.

In the meantime, as if to give stability and warrant to the former allegation, certain practitioners in different sections of the country have organized, and now the profession is threatened with another specialty; we have the Society of Railway Surgeons. We have in several of our large cities and railroad centers, hospitals owned and controlled by railway corporations, or the medical officers in the immediate employ of roads. These are maintained by the companies for the purpose of treating those of their employes injured while in their service. With those hospitals owned and controlled by individual surgeons or colleges, services are usually rendered by contract with the railroad corporations, much to their advantage; for while professional aid is procured at a minimum rate, the companies are also protected, in having their maimed or injured under such supervision, as will effectually guard against malingering; and, besides, should a civil suit arise, the surgeon is drafted into their service.

So far we have no special section at the meetings of the American Medical Association, for railway surgeons. Is it necessary to further subdivide the field of surgery? While all general surgeons are presumed to possess ample qualifications to serve their country in the field, in times of war, yet France, Germany and England have each, supplementary medical institutions to equip medical graduates for military duty.

AN EARLY SYMPTOM OF WHOOPING-COUGH.—

Dr. Huguin, of Tourteron, affirms (*Union Méd. du Nord-Est*), that photophobia with dilatation of the pupil is a useful diagnostic symptom of whooping-cough in the early stage, before the cough has become characteristic. He cites three cases in support of this position; two of the patients were children and one an adult, and in all of them the symptom referred to preceded any other manifestation of the disease.

With our rapidly extending lines of railroads, which radiate and ramify in every direction, on which more than one hundred thousand men are employed and millions of travelers ride, we can easily apprehend that the number injured annually must be very large. Do their injuries or lesions differ in their dynamic essentials, their anatomical characters or pathological phenomena, from those sustained by other causes in civil life? Do those injuries occasioned by collisions on railroads or otherwise in connection with travel or employment on them, constitute a certain and separate category of features, which are characteristic and peculiar, with regard to their local destruction and ultimate termination, and demand for their successful treatment the superintendence of one of special skill and extended experience? I think the majority will answer in the negative.

ETIOLOGY OF SPINAL INJURIES ARISING FROM RAILWAY ACCIDENT AND OTHER CAUSES.

Conditions of the spine arising from trauma in a general way, may be resolved into two divisions, viz., those in which there are distinct and definite lesions, and those in which there are functional disturbances, without any visible alteration of structure. With the former chiefly are we concerned, on the present occasion.

It has been seen that many regard railroad injuries of every description as possessing characteristic features. Everyone, who has had any hospital service, into which are entered casualty cases from railroads, has noticed that the destruction of the soft parts is very much more than is seen from other injuries, so that when amputation becomes necessary, and we trim sparingly, in a few days after, the flaps are gangrenous and we must go further up; or if we secure primary union not infrequently we will see an insidious osteo-myelitis arising; requiring a later and more extensive section of bone. It is this class of cases, too, in which we all must often notice that fearful phenomenon, of which so much is seen and dreaded by military surgeons—secondary shock.

It is important, therefore, before we can make a rational study of this question, that we ask ourselves, what a serious railway accident really is, which should give it those fearful attributes of destruction, or why they should be more common now, than formerly.

In considering the physics of the study, we must have a correct notion of inertia, momentum, velocity, power, resistance, motion and direction. A body at rest, is struck by a flying missile, the penetrating power of which is in direct proportion to its initial velocity. In studying railway injuries, or rather those occasioned by collisions on railways, we will discover the same identical laws in effect, as in the case of a

flying missile, but the picture is reversed; the human being is then in a passive, inert state, wholly beyond his own control at the moment of collision.

In the practical flight of an express train down an inclined plane, that ponderous mass of metal, the engine, and the passenger coaches are literally shot through space. In this state of motion, in making a sharp curve, or otherwise, the wheels leaving the rails, this train and its human freight, are sent onward, until the initial motion imparted by the locomotive and by increased gravity, has spent itself on the parts, in a state of inertia at the instant of collision. What gives to railway rolling stock its great destructive properties are its weight and speed. The car trucks to support their burdens, with safety, must be heavily constructed; besides, the more weighty their wheels, the more regular and easy their motion. To supply the demands of travel for fast mail and freight transportation the moving rate of speed has been very greatly augmented, hence danger, in the event of an accident, is proportionally increased.

We have then, in the modern moving train, propelled by steam, two factors indispensable for force, viz., weight and speed, which are always brought to bear on the body, in cases of sudden and violent concussions, when it in whole or part, is crushed, stretched or twisted. In many respects there is no little analogy between the spine and a train of cars. We may suppose each vertebra a car; the interlying cartilage a buffer; the ligaments connecting links and the head, the massive machine. In the center of all the *medulla cerebitalis et spinalis*, the precious freight, the passengers.

Of all the traumatic lesions which have definite and presumptive pathological lesions, arising in consequence of railway accident, or other mishaps, there are none, which have given rise to so much investigation, study, experimentation and vehement controversy, as those arising from railway accident, and which occupy the cerebro-spinal axis.

Eric Erichsen was among the first who contributed anything in a methodical way on the subject of spinal lesions attributable to railway casualties. In America Dr. B. A. Watson, of New Jersey, conducted a very extended series of experiments on the lower animal (the dog) with a view of further clearing up mooted pathological questions and endeavoring to connect symptoms with pathological changes.

Since the appearance of Erichsen's lectures we have had such a pathological entity as the "railroad spine." For he taught that the clinical features, morbid anatomy and history of certain forms of spinal injury, caused by railway accident, were unique, definite and characteristic.¹

¹ Watson, An Experimental Study of Traumatic Lesion of the Spine

Watson, on the other hand, after his painstaking, laborious and exhaustive investigation, concluded, to quote his own language, that "concussive accidents never produce pathological changes in the spinal cord, except when great force has been applied to the spinal column, and these cases generally, if not always, are complicated with a fracture, rupture and stretching of the ligaments, or severe lesions in other parts of the body, which terminate quickly in death."

Erichsen ventured to affirm that neuroses of every phase and degree, from profound melancholia, dementia or paralysis, might arise, either immediately after the railway collision, or at a remote date. His observations are mainly limited to the elements of the cord and brain with the meninges, and he takes but little notice of the part which the enveloping tissue play, either in association or as independent factors. The muscles, tendons, ligaments, extravascular supply and peripheral nerves are wholly ignored, and he looks solely for pathological changes to support his theory in the medulla and meninges. Watson's experiments having been conducted on the dog dropped through a chute, we must compare the striking difference between them and man, with respect to their physical conformation and mental attitude, before we can properly estimate the clinical application of these experiments. In one the spine is nearly perpendicular, and we must not overlook the element of fear. In the other, the spine is horizontal and has four supports instead of two, besides psychological influence is wanting. Man's head is very heavy in proportion to his size. The quality and direction of concussive force possessing but little analogy with such as is inflicted in railway accidents, we cannot unqualifiedly apply those experiments in the lesions under consideration.

Although the views of both distinguished authorities here cited are widely divergent and antagonistic in many respects, though, strange as it may appear, in one direction, at least, they evidently agree, for neither appears to attach much, if any, importance to the direful consequences to the integrity of the spine, which may follow injury of the soft parts independent of implication of the cord itself. Neither author has been able to supply anything but very scant pathological data from post-mortem examination on the human body, where death has been directly or indirectly caused by spinal injury.

In this connection an effort will be made to demonstrate by anatomical analysis and pathological observation that, quite independent of alleged morbid states which are manifested by clinical symptoms, we may and frequently do find the motor functions of the spine temporarily impaired or lost by lesions which in no way directly implicate the cord itself.

To proceed intelligently with the separative

causative factors, we must have a clear comprehension of the varied structures which we have to deal with, their relations and functions. Among the laity, and even medical circles, sometimes a most confused notion would seem to prevail with regard to injuries in the rachidian region.

What is the spine? We will be told that so and so met with an accident and has seriously injured his "spine." Lay people have a vague but singularly correct impression, nevertheless, that when paralysis immediately follows injury, the "back is broken." With our profession, the general opinion of a serious injury of the spine always implies that the cord has participated in the lesion. Neither view is correct, for we may have complete paraplegia without a broken back, and vice versa. And we may too see individuals invalidated for life when the great nerve cylinder and bony arches have entirely escaped.

The spinal column in man is maintained in the upright position by a powerful set of muscles, with an accessory set of stays, the numerous ligaments which, though permitting varied movements, firmly retain the vertebræ in position. Besides those osseous spurs given off by each vertebræ, serve as levers and are so intimately interlocked that even in the dead body they are detached from each other with difficulty.

If the vertebral column be denuded of its muscles and traction force is applied in opposite directions, the arches or transverse processes will give way often before the ligaments. As the dorsal vertebræ are firmly braced on either side by the ribs, the spine, in the event of a traumatism, will yield less in this situation, but as the lumbar region is reached lateral support is wanting, and on this the whole weight of the head and trunk is borne.

Speaking in a general way, we may say that among the manifold and varied purposes which the rachidian column serves, the most obvious and important are: 1. To form the posterior boundaries of four cavities, if we include the sacrum. 2. To support the head. 3. To carry all viscera and structures lying beneath the under surface of the cranium. 4. To provide lodgement and protection to the spinal cord.

Its weakest and most superficial segment is its most mobile; its middle the most fixed, and yet—to employ a paradox—is in constant motion, through costal action on either side. The lumbar region is the most powerful and is the center of flexion between the trunk and pelvis.

It may be well in this connection, while considering the powerful and complicated structure of the spine, to remember that that organ within the tubular canal, the cords, is but fifteen inches long and weighs but an ounce and a half; that it floats in a water bed that protects it from pressure and ordinary jars. The cervical or lumbar

segments, in the event of great and concentrated violence, permits of a distinct, lateral swaying motion, so that the momentum of force may be spent rather on the ligamentous, osseous or muscular parts, than be transmitted to the cord or brain.

Besides either extremities of the spinal column where force may be applied, either in the way of traction or compression, it may be also brought to bear from behind, or laterally. Violence, to reach the cord interiorly, must first encounter the viscera, or disorganize the spinous bodies, which would be impossible without immediate destruction to life.

Of the different regions, probably none can sustain a crush or fall with as much impunity as the dorsal. The osseous structures of the spine, here lie below the posterior costal curves and force is diffused through the elastic contents of the thorax, or one or more ribs are fractured. The same degree of violence inflicted on the cervical region, suddenly and unexpectedly, would have mortal consequences. But, when one has even a second's notice, he instinctively shortens his neck, obliterates it, as it were, by crowding it into the thorax, by raising his shoulders up to the ears, depressing the chin to the sternum and the occiput to the *vertebræ prominens*.

Accordingly we find the lumbar region the most vulnerable; for we may regard the segment as the centre of a hinge joint, and, as might be expected, is oftenest found the part which suffers in these spinal injuries, from which a patient may, for a time, survive. But the lumbar segment has a powerful and compact development; hence, simple violence, to compromise its delicate contents, must be direct and great, so that, as Watson discovered in his unique experiments on the dog, the lesion of the cord often, in itself, is of but minor importance, in comparison to the rupture or laceration of an organ vital to life.

It would be rational to assume that, in the vast majority of cases in which force operated in the cervical or dorsal regions with sufficient concussion to fracture bone, death would seem an almost inevitable consequence. In eight cases which have come under my observation, in which the brunt was borne by the lumbar spine, six died, one in six hours, two in a week, and one lived three weeks. One recovered completely, and the other left the hospital, paraplegic. There was paralysis in all these cases in the beginning. Three of them were the result of railroad accident. In all the cases, the kidney sustained associate lesions.

As far as the etiology of traumatic spinal maladies goes, my experience is mainly in harmony with the views promulgated by Dr. B. A. Watson, of New Jersey, in his experimental work on the spine, viz.: that in traumatisms of the spine, attended with paralysis, we will *always* find pathological lesions involving it, of a definite and positive description.

Prof. Erichsen, in his lecture on spinal concussion, details at considerable length a large number of cases, in which symptoms of paralysis at varying intervals after *railroad* accidents appeared. In some of these cases, there were complications of brain symptoms, with affections of the nerves of special sense. In many there were disorders of vision or hearing, melancholia, hallucinations, neuralgias, loss of memory, unsteady gait in walking, numbness and hyperæsthesia, and other ailments affecting the nutrition of the body.

In none of those cases were pathological changes present *which could be proven*, but it was assumed that anæmia of the cord existed, or that there were either chronic meningitis or myelitis.

Having seen myself a considerable number of cases of injury to the back, arising from railroad injuries, in none have I ever encountered these sequelæ. And, with proper deference to the distinguished author, yet I am convinced that his premises are unsound and untenable. And I am satisfied that his conclusions, though ingeniously constructed, will not meet with favor among those of extensive experience in the treatment of railroad injuries, or serious traumatisms of the spine.

There are, however, other serious lesions which may attend injury of the spine, which have been described by no writer in modern times, except Olliver.¹ I refer to those which are limited to the peripheral nerves, muscles, tendons, ligaments, vessels or bone; which are attributable to strain, twist, pressure, laceration or contusion, and give rise to extravasation of blood, to inflammatory exudates, synovitis, periostitis, abscess, amyotrophic changes, myopathies, thrombosis, embolism, phlebitis, cellulitis or ankylosis, and which may and often do, in early childhood, or even in middle life, be the starting-point of various organic maladies.

Extrinsic spinal injuries are very common. The vascular system supplying and maintaining the nutrition of the cord; its coverings, the meninges; the rachidean structures, osseous, ligamentous and muscular, is peculiar in its arrangement, although in many respects it is similar to the cranio-cephalic, in that there is a free intercommunication between the peripheral and the deep vessels. Hence, the explanation how inflammatory conditions are propagated from the superincumbent cellular tissues to the synovial investment of the vertebral joints, or to the elements of the cord, when the process is in relation to the cervical region.

I have on three occasions met with cases of spinal meningitis, in which the primary injury was first borne on the nates, or over the shoulders. A case of this description I saw with Dr. W. B. Fisher two years ago, in the town of Yonkers, N. Y. The patient was a young lady who, while

¹ *Traité Maladies des Spine*, ed. 1. p. 207.

on roller skates, fell on her left nates and side. She was very sore, over the seat of injury, for two or three days, the parts being swollen and tender. Soothing applications were applied, and she was confined to bed.

As the fulness and pain commenced to subside over the gluteal region, she began to complain of "pins and needles" (formication) in the soles of her feet. This was followed by numbness, and on the seventh day after injury she was completely paraplegic. On the tenth day she died, of typical meningitis of the spinal cord.

My two other cases were seen in hospitals. In one, spinal meningitis developed six days after the patient was violently clubbed by a police officer. On the second day after his castigation, his mid-dorsal region was one mass of welts and bruises. The skin over the injured area was mottled, hard and lumpy. With him, paralysis was confined to the lower extremities, but there was much more convulsive spasm of the extremities than in the preceding. His case was remarkable with respect to its termination, as he recovered from the meningitis, so that he was able to leave the Workhouse Hospital, on crutches, *three months after injury*, the paralysis not having wholly disappeared. No doubt a thickening sclerosed condition of the neurilemma of the nerve roots lingered, which might account for the nerve symptoms.

In my third case, the patient was injured by being knocked down by a passing team. Two ribs were fractured, but she was able to get on her feet, and walk home without assistance.

She was brought to the hospital on the fourth day, with symptoms of incipient spinal meningitis. The disease made rapid progress, quickly extending into the cervical section. She died on the fourth day after admission into hospital.

On post-mortem examination we found, on the left side, the sixth and seventh ribs fractured, close to the transverse processes. A large, diffuse extravasate of blood was discovered under the long, broad bands of the serratus magnus muscle, and the connective tissue on the right side. In places, it was liquid, in others partly organized, but for a very considerable radius about, the tissues were deeply red-stained by the escaping hæmatin.

The tendinous and ligamentous structures in the vicinity of the sixth and seventh cervical vertebræ were softened and thickened. On entering the spinal canal, no hæmorrhage was met with. The dura mater was greatly distended with a turbid, flocculent serum. Between the arachnoid and pia mater, throughout the cervical area, as far as the atlas, a fibro-plastic exudate was seen, which insinuated itself along the horizontal septa into the lateral sulci of columns. The medullary substance of the cord was softened in the centre, and was everywhere dotted with minute ecchymoses.

Besides those lesions which involve the cord secondarily, and have reference to propagation of irritation or infection, through the nerves, vascular channels or lymphatics, we have another important group arising from muscle or ligament strain, from contusion of the peripheral nerves, which regulate movement and nutrition of all the overlying structures, from the integuments inwards, from hæmorrhage, cellulitis, peritonitis, synovitis, arthritis, fatty degeneration of muscle, limitation of muscular action or ankylosis. The etiological factors in all the above were primarily concussive force, and conditions dependent on vital phenomena.

Sprains are commonly understood as trivial wrenches or twists of an articulation, attended with pain, swelling, and ecchymosis of the integuments. Authors give them little notice. But over-strain or violent sprain of a joint, or series of joints, attended with extravasation of blood into the articulation, with laceration of muscle or ligament, may be the starting-point of very grave organic changes, particularly in the young, or those inheriting a feeble constitution. In spinal injuries, chronic, multiple synovitis, peritonitis, softening, wasting and atrophy of the muscles, with weakening, stretching or displacement of the ligaments, are a few of the sequelæ, in aggravated cases. I have met with a case, in which a violent twist at the ankle-joint originated a diffusive osteo-myelitis which ultimately necessitated amputation above the joint.

We may have, in one or more joints of the spinal column, the same precise pathological conditions as obtain in the extremity; but as the spinal articulations are all deeply lodged, they more often escape. And, if they should be the seat of sprain, it must, during life, be rather inferred than proven.

Nevertheless, when a person comes under our observation, who is injured in the back, who has a febrile pulse and a high temperature, with a local fulness and hardness over a localized area of the spine, but in whom sensation and motion are perfect, there can be no doubt as to superficial or extrinsic nature of the lesions.

The most frequent source of injury to the ligamentous and muscular structures, is by indirect force at either terminus of the column. The dorsal and lumbar regions suffer most from this form of violence. One falls from a considerable height, or is hurled a short distance, striking on his nates or hip. The spine is bent backwards, forwards, or laterally, the inertia of the head, shoulders and trunk is mostly spent on the lumbar vertebræ.

Not infrequently, however, serious strains are induced by concussive force coming from an opposite direction; as when one is precipitated in such a direction that the point of impact is on the shoulder and side of the head, when the whole

weight of the lower trunk and extremities impinges, with great momentum, on the upper mobile, lumbar segment. These accidents, involving only the extrinsic structures of the spine, then, well deserve a careful study, for it cannot be denied that, when of a severe nature, the original pristine strength of the spine is forever lost, and locomotion will be always thereafter difficult and painful. If they occur in a maiden, she can never properly fulfil the duties of matrimony with safety; nor, in fact, perform any sort of labor requiring considerable effort.

A consideration of those infirmities of the spine, exclusive of the neuroses of the cord, following spinal injuries, opens the way for a new line of study, which may be cultivated with great interest to the surgeon and practitioner, and advantage to the crippled.

I have met with a few cases of spinal injuries in adults in which there followed absolute and permanent impairment of power, while the cord remained free.

The first case I saw with Dr. Sheahan, of this city, in which the patient, a young woman, was suffering from the effects of a fall into a deep trench on a dark night. She thought she struck on her shoulder but was not positive. She was confined to bed for more than six months and was unable to sit in the upright position for more than a year. The lumbo-dorsal muscles were markedly atrophied on both sides and the spinous processes of the lumbar vertebræ projected out so that the tips could be easily counted. There was no neurotic condition of any description. Her infirmity was local and was confined to the muscular and ligamentous structures alone. She was, when I saw her, wearing a very heavy gypsum jacket. Without it she was almost powerless to move. Her general condition was good, with a fair muscular development. There had never been any question in this case, or the two others which will be recorded, as suits for damages. It is now two years since I saw her, and her physician writes me that though she makes a living with the needle, yet she is as weak and helpless in the back as ever.

The second case was also in a woman. She was nineteen years old, and was injured while descending the steps from an elevated railroad station. She was near the surface when she slipped and fell with great violence on her back. Being unable to stand or walk, she was conveyed home in an ambulance, where she lay in bed four months. She was now examined by the railroad surgeon, who was inclined to regard her troubles as trivial, inasmuch as there was no central implication of the cord. At this time she was admitted in the hospital. On examination in the lower lumbar region it was evident that an abscess was forming close to the inner border of the quadratus lumborum muscle. On freely

incising it a fistulous tract was discovered extending down to the transverse processes of the second and fourth lumbar vertebræ. By enlarging the wound, we came down on those processes of bone which were necrosed, and with the gougers cut them away. There was a considerable area of diseased tissues along the line of the sinus, which was scooped away. The incision healed by granulation, beginning at the bottom, but it was more than three months before it closed in entirely. She now occupies a position in a dry goods store, but there remains a rigidity of the muscles of the back, which greatly limits the normal stooping movement and prevents her from occupying her former position.

My third case of permanent impairment of function following severe injury of the back, was a carpenter, who while in a stooping position was struck over the lumbar region by a falling piece of timber. I saw him shortly after he was injured. There was no palsy, but his spine was rigidly fixed and over the seat of injury there was great pain. He passed blood in his urine, both as coagula and in the fluid state, in such quantities as to threaten fatal anæmia. By the aid of refrigerant drinks and cold applications on the nephritic regions it gradually lessened and in a few days completely ceased. This man had a slow and painful convalescence. For many months he could not maintain the trunk on the femoræ in sitting or walking, without making a lumbar support, and for three years he was an invalid. For a long time there was a marked and considerable fullness over the left kidney, whether attributable to hæmorrhage beneath the capsule into the parenchyma or stenosis of the ureter with hydronephrosis, we are unable to say. It, however, gradually diminished in size and ultimately disappeared.

These three cases constitute all the lesions of an extrinsic character clearly attributable to overstrain or contusion of the spine, in which permanent disability in varying degrees have followed injury, that I have seen.

In the treatises and brochures of Abercrombie, Guthrie, Brodie, Cooper, Ollivier, Chapponeare, Duplay and Richet many cases of this character are mentioned but not fully described.

In analyzing the phenomena of those painful neuroses over the long axis of the rachidian plane, we cannot forego at least a cursory examination of the nerve supply, of the meninges, the bony framework of support, the soft parts and integuments.

The dura-mater is supplied mainly by extremely delicate prolongations inward of the sympathetic through the intervertebral foramina, and by ganglionic fibres from the nerve roots which pierce the neuralemma, and are reflected inward and upward in opposite directions.

The deep osseous tissues, ligaments and cellu-

lar elements in the dorsal region, are provided by the posterior ramifications of primary division of the twelve dorsal nerves. The anterior branches of the six lower dorsal nerves supply the three sets of muscles which laterally wall in the abdomen.

The arrangement of the lumbar nerves is similar to the dorsal, but it may be noted, in all the regions of the vertebræ, that, beginning in the superior segment, the cervical nerves send prolongations into the thoracic region and freely inoculate or are blended with its nerve-trunk, the dorsal with the abdominal, and the lumbar with the pelvic or sacral nerves.

As a result of violence to the spine we may have hæmorrhage, laceration of substance, inflammation, peripheral paralysis or neuritis. The consequences arising from these various conditions are important or serious in proportion to their extent, the age of the patient, sex, and the condition of health. One of those pathological conditions may be dependent on the other. For instance, sanguineous extravasation into or along the muscle sheaths, if properly treated and of moderate extent, will rapidly disappear. But under varying circumstances it may give rise to irritation, inflammation or suppuration. Local inflammation may be confined and its spread prevented.

As a rule, however, unless very great injury has been inflicted, the processes of repair in the spinal coverings are rapid and complete. This may be explained partly, perhaps, by their greater vascularity and elasticity.

There are, nevertheless, occasions when a muscle is subjected to sudden and considerable strain; the result may be very serious. Such we sometimes meet with, in those cases of irreducible luxations at the shoulder joint, in which the muscle has lost its elasticity with contractility, and we fail to reclaim the head of the humerus in position after replacement. Dire results may follow rupture of the meningo-rachidian veins. Their walls are very thin, hence, when ruptured, fail to close in the rent. Bleeding from these vessels is a most prolific source of secondary inflammation, of the meninges and pyelitis, by pyogenic processes, propagated either through the lymph channels or the blood vessels, which, in this situation, communicate very intimately.

Primary and direct disorganization of the osseous structures of the spine, without mortal implication of the medulla-spinalis, or such a lesion as will at once and permanently destroy the conducting power of the spine below the area of contact, is very rare.

Pathological changes involving the bones of the spine, after injury, are mostly secondary, and are not often seen, except in early life. Even then, when met with, after an alleged injury, it might become an important question to decide

just what part the traumatism exercised as an etiological factor in the initial changes, or whether or not the necrosis or caries was rather attributable to influences originating within the organism itself, the development of which, immediately following accident, being rather an adventitious circumstance.

The same observation might apply to synovial implication of the manifold articulations of the spine.

In all grave spinal traumatisms, provided the patient receive immediate shock, spinal-meningitis arises, and, in time, the brain shares in the changes which commenced in the cord. Hence, when the basillar membranes are reached, and those of the medulla-oblongata, the respiratory centers become the theater of inhibitory action, and life is quickly terminated.

The subarachnoid cavities of the brain and spinal cord freely communicate. In serious injuries of the cord we often have premonitions of approaching dissolution, accentuated through the nerves coming from the cord, within the skull, while all the mental faculties are yet undimmed, and the patient himself is warned of the terrible change which awaits him only by indications made manifest through those nerves which preside over respiration and phonation.

Very much has recently been written concerning what is designated "concussion of the spine"—a condition which has no definite pathology, and the existence of which is mostly based on a series of vague and ambiguous symptoms. In other words, it is revealed mainly by clinical phenomena.

It is alleged that its striking characteristic is the fact that it manifests its effects only after the lapse of considerable interval from the time of injury; is exceedingly insidious in its onset, but withal, may have a speedy and favorable termination; that it is always followed by psychical disturbances of an emotional character, impairment of vision, ataxic symptoms, unsteady gait, pain in the back, headache, and a general breaking down of health.

Many distinguished authorities agree that as a result of violent physical shock, we may have a condition of the brain or cord in which there are well-marked evidences of serious pathological disturbance, and yet, after death, no gross lesions of structure are found to account for them.

No one who has examined many bodies of men or women who have come to their end by a catastrophe but must admit that not infrequently practically nothing can be found which unequivocally accounts for death. Yet, from my own experience, I feel confident that in many of those cases set down as spinal concussion, wherein there is no shamming, pathological changes may be discovered which will account for symptoms.

It is preposterous to assume, then, when vio-

lent and concussive force is applied to the body, that that slight, delicate cord, firmly enclosed by the dura-mater, and protected within a powerful, bony wall, will suffer detriment, while the exposed, friable viscera escape.

Dr. B. A. Watson's experiments on animals have definitely decided this question.

The spinal cord, we are told, may become anæmic. The patient, they say, has "anæmia of the cord." It is said to be a morbid condition which arises solely as a result of railroad accident.

A most ingenious theory has been devised to connect cause and effect in this new addition to our nomenclature of disease.

The imagination and credulity of the observing and thinking student are strained to the utmost to reconcile many of the unsupported theories and allegations of its discoverers and votaries.

In order to maintain the theory, and give force to reasoning, something more is demanded than hypothetical assumption and illogical conclusions.

It is imperative and proper that the profession be enlightened on some of those moot points, which have been ignored or warily evaded by those who have written most on this mysterious disease. In the beginning, we must be convinced that the emotional state of terrible alarm, trepidation and suspense attendant on a railway collision are different in quality and magnitude from those which must be of frequent occurrence in the carnage of battle, during the firing of heavy guns, explosions of shells, and springing of mines, from that borne by the wounded when a whole limb is torn away, or when the maimed and crippled, unable to withdraw their mangled, bleeding bodies, are ridden over, or trampled on, by the columns of advancing cavalry or artillery.

Can the horrors of railroad calamity exceed those which accompany the crashing destruction of a thunderbolt, when it falls with destructive energy on a dwelling, lifting it off its foundation, cleaving it in two, killing outright, in an instant, one or more individuals, yet, with the survivors, how many of them suffer from spinal anæmia?

In our large cities, with their numerous, enormous modern apartment houses of great height, from which occupants or mechanics often fall in every attitude of the body, here, accordingly, the hospital surgeon will meet with every variety of spinal injury. In no case which I have ever seen of spinal injury was there ever observed by me that mental aberration which is said to constitute that condition which is said to be an integral part of spinal anæmia.

Next in importance to those symptoms reflected through the organ of the mind in spinal anæmia is that condition in which the spinal

cord is the seat of pathological changes, or rather its molecular, vascular elements.

It is not clear whether we are to understand by this, that the quantity of the blood present is diminished, or whether its nutritive, reconstructive elements are deficient, for the demands of the cord. Presuming that the pathological condition can exist, as a sequelæ of a violent shake of the body, there is no difficulty in the way of arraying symptoms almost indefinitely, as arising from or dependent upon it.

But, what proof is there from an anatomical, physiological or pathological standpoint, that such a condition is probable; that such a phase of spinal disease is possible; that the vascular supply to the spinal cord is obstructed, diminished or altered, so that its nutrition is disturbed, or that its cellular elements are impoverished, while all the other organs of the body are functionally active? Organs stimulated by the same nervous systems, the same blood current, under the same physical laws and influenced by the physical and chemical changes.

All such proof is totally wanting; nay, on the contrary, in mechanical anæmia of the organ or limb induced by the surgeon, there is no analogy whatever, to the symptoms resulting and those said to be associated with "spinal-anæmia." On ligation of the femoral artery, as it emerges from under Poupart's ligament, we will notice a cooling of the limb arising from the emptying and collapse of the peripheral capillaries and loss of heat. Owing to venous stasis and temporary diapædesis, there is a sense of fullness in the connective tissues; but usually no pain, except where the ligation was applied and perhaps a nerve branch was injured.

With the brain itself, although one or both of the carotid currents is dammed back, we may immediately notice the physical effect resulting; yet nothing will present itself, having the slightest analogy to this new disease. We have other instances of mechanical, accidental, or pathological exsanguination in which every organ must contribute its share in the general loss, the spinal cord as well as others, but the local impoverishment of the spine, here, is not demonstrable by any special symptoms.

From the foregoing, it is evident that there is absolutely nothing whatever, which should permit the continuance of a supposed pathological entity which has no substantial existence. We have no right, in these days, when instruments of percision are at hand, to assume the existence of a malady demonstrable, if at all, rather by therapeutic than pathological proof. It being supposed that certain functional disorders are present, which indicate impoverishment of the cord, medicines are given, which supply tone to the muscles, enrich the blood and act as a spur to the nervous system. But it is inconceivable

how one can infer from therapeutic induction alone, that the spinal-marrow is the center of a morbid change, when the system responds to constitutional tonics or alteratives that act on every fibre in the organism. It would be just as illogical to argue that there was a localized anæmia in the sciatic nerve, when, through some acute malady, the bodily strength is at a low ebb.

The actual pathological condition which the patient suffers from, in so-called spinal-anæmia, is unquestionably a peripheral neuroses, of a neuralgic character. As a matter of observation, it is well known—that along the central and lateral planes of the spine there are local diseased areas, whose principal manifestations are pain and hyperæsthesia. This pain may be localized or diffused; constant or intermittent. It is usually regional. It is a condition of adult life, and is much more common in women than men.

There is always a well-marked derangement of the general health. The hepatic functions are languidly performed. The patient has loss of appetite and is constipated. He is pale, leucocythenic and weak. If a woman, there will be menstrual disturbances. What constitutes its essential clinical differences in the sexes, is its local, neuralgic manifestations, its seat of selection.

With the male sex it is very uncommon, though when it does arise, its location will be in the lower lumbar and gluteal regions; or those parts supplied by the peripheral, or muscular ramifications of the posterior division of the lumbar and sacral nerves. Then we will have what is designated lumbago or sciatica.

With woman, these neuralgias generally radiate through the nerve-filaments from the anterior branches of the six upper dorsal nerves, on the left side, and also, along the pelvic fibres of the anterior crural, which penetrate the ovary. Here, too, singularly, pain is most frequent in the left side.

These neuralgias, intercostal and ovarian, then, are a consequence of a general debility, malaria, and functional disturbances, and are not dependent on traumatism of the spinal cord.

These neuroses belong to that class in which the faith-healer and charlatan reap a rich harvest; or in which anyone, who can make a sudden and positive mental impression on the mind, will meet with marked success, when internal medication fails.

Many phases of this, so-called, anæmic spine, will yield to internal, reconstructive remedies, as quinine, iron, arsenic or mercury; good dieting, sea-bathing, change of air, travel, faradization, shampooing, massage, dry cupping, plasters, etc.

The above may seem rather a digression from the strict text; but under the circumstances, it forms an important constituent of our theme, as it is, in reality and fact, no fanciful or imaginary

picture; but is a truthful résumé of what has evidently been erroneously designated "anæmia of the spine."

I have endeavored to completely demolish the artificial and unstable foundation on which it rests, and tried to demonstrate that this "*rail-road* spinal anæmia" is a myth; but is, unhappily, often a source of distress among many who have never seen a railroad.

Having so far considered the etiology and clinical history of those lesions and derangements attended with definite and precise pathological changes, and other maladies assumed to succeed concussive force applied to the back, it is now necessary to extend our field of inquiry from the parts which directly enter into the composition of the spine, to the cavities which it posteriorly walls in, the abdominal, thoracic and buccal.

The abdominal cavity contains four fixed, solid organs, dependent and suspended, having no bony encasement, and lying immediately anterior to the flexible lumbar curve, and are frequently exposed to injury from indirect violence.

It is in this situation, that is most frequently seen, destruction, limited or extensive, from transmitted force; as when the liver, kidney, a distended stomach, bladder or gravid uterus, suffers laceration or rupture.

The renal organs suffer most frequently. Their juxtaposition to the spine, behind the peritoneum, when their meso-nephron, or the enveloping layers of fibro-cellular tissue, is dense and firmly fixes the organ in position.

With the exception of grave injury of the cord, as a complication, I had never seen but two cases of injuries of the back in which there were evidences of kidney complications in extrinsic lesions. One of those cases, a physician, who, while aboard what is known as a cable-car, was injured. These cars stop and start suddenly; so that, unless managed by a competent gripman, there are almost constant jars and starts, in their working. He had but entered the car and was advancing towards the front, when it gave a lurch forward, throwing him violently backwards against the iron-arm of a seat. The doctor was unable to rise unassisted, and suffered from shock for several hours. The day following injury, he had hæmoptyses and bloody urine. By proper remedial measures combined with rest, after ten days the hæmaturia ceased, and he was able to sit up. His recovery to health was slow, though in time he quite regained his former vigor.

I have never seen hepatic disorganization, as a sequence of spinal injury, unless mental force had been sustained.

This leads me to infer either one or two things in this connection. The liver may suffer peripheral or central disintegration, when this does

not involve the large blood-vessels, with quite unique impunity, as it undoubtedly possesses within itself the property of complete and rapid repair. It may, perhaps, be partly attributable to its situation which, when attentively studied, will be found to have a configuration and position which effectually provide against extensive damage by violence, and guards it against sudden concussive force. It has long been a matter of observation by physiologists engaged in experimental work on the liver, of lower animals, and by surgeons operating on hepatic structure, that if the primary gush of blood could be controlled, little difficulty would be experienced; as the triple compound, circulating through the lobules, possess marvellous hæmostatic properties, and plastic inflammation with rapid coaptation, was the rule.

Only the free, thin-edged borders of the liver are exposed. The solid, compact mass of this organ, has a broad and intimate attachment to the inferior surface of the diaphragm. It rises high up under the shelving margins of the ribs and rests on a surface well calculated to receive and scatter concussive force, as it lies at its anterior, superior, and greater part of its posterior border on an air-cushion—the highly elastic and expanding lung.

I know of no recorded case, wherein the spleen suffered laceration in connexion with spinal injury.

The stomach in a distended state, lying on its posterior surface, in immediate contact with the vertebral bodies, one might expect, would easily rupture. It, however, is singularly invulnerable to physical shock.

Certainly, it goes without saying, that violent concussion, sustained, through transmission, by the uterus, when impregnated more than three months, almost inevitably leads to abortion or premature delivery.

The contents of the thorax, the circulatory and pulmonary organs, are seldom involved in severe injuries to the back. Very often, force brought to bear will so compress the chest antero-posteriorly as to induce multiple, costal fracture. The pulmonary parenchyma is very tough and will resist great pressure. I have never seen rupture of the heart from concussive force, through the dorsal region; although Watson has observed such a complication in his experiments.

An injury of the cervical vertebræ sufficient to compromise the integrity of the buccal cavity, alimentary or air-passages, must be almost inevitably fatal.

MORBID ANATOMY AND PATHOLOGY OF TRAUMATIC SPINAL LESIONS.

Morbid changes of structure, resulting from injuries borne by the spine, vary according to manifold circumstances, to the quality and force

applied; the time intervening from the accident; the age and condition of the patient; the extent of parenchymatous changes and degree of reparative effort.

If the violence have been shortly followed by death, little will be noted, except extensive laceration of the parts, with disorganization, partial or complete, at the seat of injury. There may be ecchymosis of the integuments and evidence of some bleeding in the underlying tissues, its quantity and quality being dependent on the degree of shock, heart depression, chemical and vital changes.

I have frequently noted that when the bleeding is eccentric to the spinal canal, the blood is commonly more or less coagulated; but when within the bony rings of the vertebræ, whether intra- or extra-meningeal, is always of a dark liquid consistence.

In those who have succumbed from lesions entailing much loss of blood, with compression of the cord resulting therefrom, I have invariably found the hæmorrhage located *external* to the meninges spinalis, and coming from the laceration of the meningo-rachidian or the longitudinal spinal sinuses.

Intra-meningeal hæmorrhage, either from the fine capillaries on the serous surface of the dura-mater or the medulla-spinal veins of the columns, horns, sulci and substance of the cord itself, I have never seen. Possibly it may occur as a pathological process in certain constitutional maladies, but as a result of an injury it can never occur, except in connection with mortal destruction. It is well to remember that the cord, weighing but an ounce and a half, has but from sixty to eighty drops of blood ever circulating in it, that it is swung in a chamber holding nearly three ounces of fluid, by which it is surrounded on every side, and nowhere comes in contact with the bony walls which enclose it.

Hæmorrhage within the theca seldom is seen, *post-mortem*, to rise above the mid-dorsal region. The adjacent fibrous tissues are always deeply stained and occasionally the hæmorrhage will find its way outward through the inter-vertebral foramina in the direction of the nerve-trunks.

I have not yet seen any cases in which advanced changes in the direction of this integration were noted.

When hæmorrhage has been considerable, not disappearing by absorption, we will find associated with it changes attributable to congestion and inflammation. The vessels on the thecal and serous surfaces of the dura-mater are greatly distended, the subarachnoid fluid is turbid, and small flakes of lymph may be seen floating in it. In places the pia-mater and arachnoid are glued together, by adhesive inflammation. The cord itself is softened, and under the microscope are seen along the periphery of the white matter

round cell infiltrate with leucocytes and granular matter intermixed.

All the membranes are markedly thickened and have a deep congested hue.

The soft tissues overlying the spinal cord in spinal-meningitis, as with all other tissues which overlie an inflamed serous membrane, as those of the abdomen, thorax and skull, are always considerably thickened and distended by an inflammatory exudate.

There will be found at times, evidences of bone implication, synovial destruction within the capsular ligaments, and sero-purulent formations.

The pathological changes observed during life after spinal injuries, are important to correctly comprehend. They may, for purposes of description, be divided into four classes: 1. Eccentric lesions; 2, centric lesions; 3, organic lesions; 4, functional disturbances.

Eccentric lesions are those of the structure which are situated external to the spinal canal and involve the bony architecture, the motor leverage, circulatory system, mainly, and peripheral nerves. They are dependent on pressure, tension or laceration. In the vast majority of cases, being of a trivial nature, they give little inconvenience; but when the back has borne great and considerable force, we may witness such lesion of muscle or other structure as will cause temporary or permanent loss of function. If inflammation supervene, the residuum of its deposit may undergo fibrous changes and so bind the sinewy structure together, as to occasion muscular ankylosis, pressure on the nerves or blood-vessels and amyotrophic changes, in all the tissues. If the integuments and the subjacent tissues are lacerated we can readily comprehend how, through the intimate connection between the dorso-spinal and meningo-rachidian vessels, septic processes may be transported to the enveloping membranes of the cord.

Primary congestion or inflammation in the inter-muscular connective tissues seldom give rise to organic changes, and readily subside. But a severe injury, the widespread effects of which involve *en masse* all the tissues, may be followed by a low grade of inflammation, implicating the vascular supply, giving rise to a phlebitis or strombosis of the superficial or deep veins, in this manner seriously interfering with nutrition and inducing a softening or wasting of the muscles. The bony structure of the spine usually escapes an injury unless great violence is borne. In children, however, this immunity does not obtain, especially when tubercle is inherited.

In fractures of the spine, so-called, everything will depend on the direction which the fragments have taken. If the broken bone be crushed in, on the cord, we will have hæmorrhage, inflammation and softening, while if there be slight displacements, the cord may escape. We have

no proof that the bones of the spine will regenerate; certainly if they are allied anatomically and physiologically with those of the cranium, which is claimed by some anatomists, then they are destitute of osteogenetic power.

Simultaneous or consecutive osseo-arthritis changes of an inflammatory nature in the vertebral joints seldom extend to the cartilagenous pulp between the bodies in the absence of constitutional cachexia. The pain along the spine in various regions according to where concussive force is applied, is dependent, I am convinced, rather on a low grade of cellulitis, involving the muscles and tendons, than a peripheral neuritis.

Centric lesions of the cord, accentuated by clearly defined symptoms and resulting from trauma, are very seldom met with. Although I have seen and treated now more than one hundred and fifty cases of fracture of the vault of the skull, up to the time I reported them in Oct., 1890 (Trans. New York Medical Ass'n., 1890), and saw more than fifty fractures at the base, besides very many cases of cranial injury in which spasm or paralysis followed and the patients recovered; in that seventeen years experience I had under my care but ten spinal injuries of an intrinsic character, so that on a reasonable calculation, in falls, blows, or collisions, it may be said that the proportional injuries of the cord with that of the brain under those circumstances, was rather less than one to twenty.

As the spinal cord cannot be stretched nor sundered by concussion, we must direct attention mainly to the effects of pressure; pressure by bone, luxated or fractured, or pressure by blood; by an excess of serum, lymph, a plastic exudate or pus.

Should a large spicula of bone be driven in or through the meninges, the cord is irreparably disorganized beneath it. Fractures of the lateral arches, involving the transverse processes, imply great violence, and I believe are always fatal, either immediately or remotely. The spinous processes in slim subjects being very superficial, give way to force most frequently; but owing to their inclined, overlapping adjustment and numerous ligamentous supports, are dislodged with difficulty. When bone pressure is moderate but constant, along with producing paralysis, involving the motor or sensory nerves, or both, it gives rise to meningitis and myelitis. Before necrotic processes of the osseous structures is complete, the patient has usually succumbed.

Intra-spinal hæmorrhage, after severe injuries of the back, by pressure, may induce temporary paralysis, meningitis or molecular degeneration of the medullary substance. The pathological changes which it induces are those characteristic of pressure exercised by a solid substance. The effused blood being confined within an air-tight chamber, in which the circulation is necessarily languid, absorption is slow and imperfect.

Spinal meningitis, resulting from trauma as a primary affection, is very rare, except in the presence of fracture. Commencing as a local and well-defined affection, its tendency is to spread upward into the basic meninges of the brain.

The peripheral sensory nerves in spinal meningitis are always morbidly susceptible to impressions, and the reflexes in the early stages of the malady give rise to intermittent or constant spasm of the muscles.

Authors have in turn framed different theories to explain the predominance of one phenomenon over the other in those meningeal inflammations, when at one time we will have anæsthesia or hyperæsthesia in a limb which is motionless.

They have sought to justify and prove their conclusions by experimental physiology, ascribing one set of symptoms as attributable to pathogenic changes in the antero-lateral columns of the cord; another, to the posterior columns; to the grey matter and white substance, alternately. These views are, however, merely speculative, and are lacking the confirmation of post-mortem examination. Admitting, nevertheless, their scientific accuracy, it would, as far as we know, in no way aid their surgical management. Meningeal inflammation, although, as its stages merge one into the other, thus inducing pain, spasm and paralysis of the lower regions of the body, is compatible with consciousness and life, until the upper cervical segment of the spine and base of the brain are involved.

Irregularity of cardiac and respiratory action, with twitching of the facial muscles, loss of speech and the power to swallow, slowly developing deafness and dimness of vision, announce that the roots of the cranial nerves are involved and that the end is near. As we invariably witness spinal manifestations in cerebral meningitis, so in grave spinal meningitis the vital and psychological functions of the brain never escape. Organic lesions of the cord, arising independently of constitutional causes, are infrequent.

The medulla-spinalis is seldom involved in inflammatory processes without the participation of the meninges, the latter being the primary structure to take on inflammation.

When the spinal marrow undergoes interstitial or molecular disintegration, as a result of trauma, along with constant pain over the integuments of the back, which often, too, is reflected along the sensory nerves into the extremities, we will see paralysis, spasm or hyperæsthesia, which will correspond with that area of the cord supplying the affected group of muscles.

As I have never seen the seat of traumatic pyelitis or pathological changes limited to the cords alone, post mortem, I cannot speak from personal observation; nor can I find such a condition even mentioned by such world-renowned pathologists as Virchow, Paget, or Billroth.

We must turn to medical pathology for information relative to those fine structural changes which occur in the pulpy matter, for, no doubt, like pulmonary tuberculosis and Bright's disease of the kidneys, those microscopical changes in the nerve-cylinders invariably depend on systemic influences solely, and not on violence of any description; hence what has been written so fully relative to pathological changes in the spinal marrow has but little application to surgical or traumatic lesions of it.

Of the functional neuroses of the spine, their name is legion. In a surgical essay on spinal diseases, their consideration from a pathological stand would seem a work of supererogation, if it were not claimed that many of them had their starting point in an injury. They have been designated spinal anæmia and spinal congestion, spinal concussion, etc., and one author (Hammond on the Nervous System, page 217) has even gone so far as to further subdivide them on a physiological basis into anæmia or congestion of the antero-lateral and posterior columns. An imaginary pathology has been elaborated, with considerable detail and circumspection, to correspond with the views and notions of the authors, and we are told now that precise localization of spinal lesions is a matter of great simplicity. We are told that certain cells within the grey matter and white substance degenerate and regenerate under the influence of the circulation, which, at one time, is excessive and another diminished; that one train of symptoms is dependent on one phase of the blood supply, another on a contrary. Now, as no one has yet been able to demonstrate by an autopsy the pathological changes, if any are present, the necessary proof is wanting to support these assertions.

These allegations are dependent wholly on empiricism. When subjected to the rigorous test of scientific analysis, they fade away into nothing.

Very many of these spinal neuroses of a functional nature are chiefly hysterical, epileptic, or choreaic, probably dependent on hereditary influences, sex or habit, which act through the blood. Their pathology cannot be definitely written yet, for it is not understood. Without question, however, we may rather look to the cerebral organs for the central trouble than the medulla-spinalis.

THE DIAGNOSIS OF INJURIES OF THE SPINE.

Before the days of Lænnec, every species of acute inflammatory affection involving the lung, its parenchyma, its tubular structure, and serous investment, was designated "a pleurisy," and all were treated on the same general principles, by essentially the same remedial agents. But there came forth a genius, who applied the revelations of physics to vital phenomena within the

human body, and he taught how, by the aid of the eye, the ear and the tactile sense, we might not only recognize the different structures involved, but that we could, with certainty and precision, estimate the progress or retrogression of the pathological changes within them. Now, though of great value, this application of physical laws to the elucidation of pulmonary diseases, for diagnosis and prognosis, yet the late famous clinical teacher, Thomas Watson, said, in speaking of pulmonary disease: "It may seem paradoxical, but the very perfection of the physical diagnosis of pulmonary diseases, has often constituted an impediment to their treatment."

Spinal diseases taken collectively, as a whole, were in the same chaotic state, at the beginning of the present century, as were maladies of the lungs before the days of Lænnec. But through the discoveries and experiments of Magendie and Bell, the functions of the nerve roots are now known, and by the aid of Brown-Séquard and other experimental pathologists, we have been made aware of the special properties resident in the columns and matter of the cord, itself.

Surgical pathologists have made it possible for us to differentiate the inflammations or pathological changes in the various structures which envelop the medullary cylinder, from within outward. And hence, to-day, not as formerly, we are enabled to speak definitely of the idiopathic or traumatic affections which may occupy any area of the spine, or its organic components.

It may not be always possible to effect a definite diagnosis immediately after an injury of the spine has been sustained, unless very great violence was applied, and the cord itself suffered direct and positive pressure from displaced bone, or fracture, under which circumstances, complete and instantaneous paraplegia is invariably a symptom of mortal omen.

At the first visit to our patient, we may find him suffering severe pain in all the joints below the sacro-lumbar articulation and upward along the lateral planes of the spine. He is unable to raise the body or elevate the lower limbs without very great difficulty, even if it is possible at all. He has perfect control of his sphincters, and sensation is nowhere impaired.

The family, friends, or patient himself may now demand of the medical attendant information as to the nature and extent of the injury. This cannot be stated at this visit, but I feel assured, from my own experience in a large number of spinal injuries, that, however, it will seldom require but a very few days before we can, with certainty, say whether the spinal marrow is involved or not. Hæmorrhage, inflammation, serous or purulent effusion, will present symptoms of such a clear and unmistakable type, that one cannot be deceived or incapable of interpreting their clinical significance.

The most serious, but infrequent, lesions attending violent injuries to the back, are those which have reference to the cord and its membranes.

These are of a primary and secondary character. With the former, we are promptly apprised of direct medullary implication, by the presence of paralysis in the lower members, complete or incomplete. Primary paraplegia after the injury is usually induced by pressure, which effects the disorganization of the cord, destroying its conducting power. We are not always able to precisely define the exact situation or extent of pressure, for an arch or lateral plate of vertebra may have been fractured and forced into the spinal canal at the time of accident, but, owing to the elasticity and strength of its connecting ligaments, with the rebound, it is retracted away from the indented cord. And, on examination, although there may seem some slight increased mobility of a projecting vertebral spur, we cannot always assume that there is displacement.

As a diagnostic aid, we might have recourse to an exploratory incision, so as to effect a more accurate estimate of the effect of the injury, and to guide us in the way of treatment.

But, although this might be a theoretical advantage in serving a dual purpose, yet practically it cannot, only in very exceptional circumstances, be regarded as a permissible procedure. Possibly, under extreme circumstances, might a free incision into the tissue be allowed as a therapeutic measure—as a diagnostic, almost never.

Fortunately, in the presence of total inhibition of the spinal or neural functions in the lower extremities, we may pronounce the lesion in the spinal cord one of an irreparable character, resulting from direct and permanent disorganization of such a description that, even though the cord were stripped of its investments and completely accessible, we are powerless in the way of instituting remedial measures.

Traumatic compression, laceration, or disintegration of the spinal cord, accordingly, may be said to be a condition of easy diagnosis, when complete paraplegia is present. Certainly, when bone is fractured, but is not displaced, and no symptoms are present indicative of paralysis, we cannot, in the deeply buried lines of the back, always make an immediate diagnosis. It is of little consequence under these circumstances, however, that we fail to correctly ascertain the extent of lesion, for it will in no way influence remedial measures, or affect prognosis.

Unfortunately, however, when the cord and its membranes become secondarily involved, some days or weeks after injury, diagnosis is attended with many perplexities.

Next to osseous pressure, in producing organic changes in the spinal cord, will come hæmorrhage.

Paresis following hyperæsthesia within twenty-

four or forty-eight hours of the injury, will be suggestive of intra-spinal hæmorrhage. Its volume may be estimated by the extent of paralysis and the areas affected. When the viscera supplied by the lumbar plexus show evidences of paralysis, and the sphincters of the bladder and rectum fail to act, we may assume that the effusion has mounted up to the dorso-lumbar junction.

It may require a very nice discrimination in diagnostic tact to differentiate, at the outset, intra-spinal hæmorrhage from meningeal inflammation. But the patient's exsanguinated condition, the deep-seated pain from pressure, the absence of chills, acceleration of the pulse and of rising temperature, all point to the exclusion of inflammatory changes having yet occupied the meninges.

Our diagnosis of intra-spinal hæmorrhage will be corroborated if, within a week's time, amelioration of the symptoms is present, and restoration of function is being gradually reëstablished.

Extensive hæmorrhage from the dorso-rachidian vessels, when profuse and localized as an intra-muscular hæmatoma, may be recognized as a sanguineous effusion which, in the healthy individual, rapidly vanishes by absorption.

Changes of an inflammatory character in the spinal cord are manifested by a diversity of symptoms. First, by constitutional phenomena, which profoundly impress the nutritive processes and local conditions. The patient has fever, quick pulse, rising temperature, is thirsty, has neither sleep nor appetite.

There is always pain in the back in traumatic spinal meningitis, associated with extreme peripheral tenderness, localized or extensive anæsthesia along the extensor or flexor surfaces of one or both limbs. Thus a clonic spasm, unilateral or symmetrical, is always present, provided there has been no implication of the medulla. When there is this association, the cord having lost its connective power below the seat of lesion, spasm will be noticed only above this limit.

We are perhaps justified, in the presence of a certain set of symptoms, in assuming that we may, at the outset, be able to localize the limit of meningeal inflammation. This would seem all the more positive when, in the presence of every symptom of incipient meningitis, we succeed, by the active interposition of therapeutic resource, in arresting its progress. Accordingly, we may assume that the lumbar segment, the cauda equina, is the primary and only region affected when paralysis, paresis, hyperæsthesia, spasm or muscular twitching, is confined to the parts supplied by the nerves whose roots are located in this district. Stiffness, pain or spasm in the muscles supplied by the lower dorsal segment, those muscles animated by the lower six dorsal nerves, viz.: the deep spinal muscles of

that region and the three sets of muscles which anteriorly and laterally wall in the abdomen, the external and internal, oblique and transversalis. Hence, the muscles of the back are hard, stiff and unyielding, and it is noteworthy at this juncture, that the patient begins to complain of a most oppressive sense of weight and constriction over the abdomen, which he compares to being drawn tightly by an encircling cord, the abdominal muscles pulling in an opposite direction; or having a heavy weight resting on the præcordia. The movable wings of the thorax are locked and fixed by an intermittent spasm of the lower intercostal muscles, and respiration is maintained principally, now, by its auxiliary muscles, the cervical and scapular, with the aid of the diaphragm.

Meningeal inflammation having compromised the entire dorsal district, we have anticipated it, as it were, *i. e.*, knowing, when this area of the arch is invaded, our patient—whose mental faculties remain as yet unclouded—is warned of his impending danger, and given time to prepare himself and arrange his affairs—as, with but another slight advance into the cervical region, the implication of post-thoracic and the phrenic nerves, when asphyxia will terminate the struggle.

The diagnosis of cervical meningitis is unimportant, as the general meningeal disease is wholly beyond our control, and swiftly fatal, when this area is occupied.

I have seen in several fatal cases, a rather singular clinical phenomenon, in the upward march of inflammatory changes. It was this: that whereas the extension of the disease, from the lumbar to the lower dorsal district, may occupy several days and be extremely insidious in its advance, but, when it was finally manifest in the dorsal segment, it often, within the lapse of a few hours, spread into the cervical region and quickly terminated life.

CONCLUSIONS.

In dealing with the foregoing subject, my aim has been to compress within a small compass as much as possible, without omitting any important detail; but I fear, with the space at my command, in this I have but partly succeeded. Quotations and the historical part of the subject have been largely omitted.

In presenting the study of spinal lesions my object has been, rather, to make it clear and comprehensive than to confine myself rigidly to any arbitrary arrangement of matter; for, regardless of what pains may be taken in constructing an article, under various headings, the divisions and subdivisions are often more relative than absolute.

Very little or no notice at all is given to the subject of traumatic lesions of the spine, in text

books, or even encyclopædic works on surgery; hence, we are justified in assuming that serious injuries of this structure are rare, or else, that surgeons have given them very little attention.

An attempt has been made here to isolate the complexity of lesions following severe injuries of the back, and not confound the consequences of one with the other, to demonstrate that grave injury may be sustained in the rachidian region without any implication of the cord.

Accordingly, in the light of our present knowledge, and after a careful study of normal structure and function; the physics of force which give rise to spinal injury; experimental investigation, clinical phenomena, pathological changes and morbid anatomy, it may be definitely stated:

1. That in the vast majority of cases in which complete paraplegia immediately sets in, after spinal injury, it may be assumed, with almost positive certainty, that the medulla-spinalis has sustained a palpable lesion of its integrity, which usually ends mortally.

2. That there is no proof that mere concussive force will either simultaneously or consecutively ever lead to paralysis, without inducing well-marked and positive pathological changes in the anatomical elements of the cord.

3. Physical force and the psychological effects of fright being the same in railroad as other injuries, there is nothing to justify the claim that there are grave lesions of the spine resulting from railroad collisions which are characteristic and peculiar.

4. There being no proof of the existence of such diseases as anæmia or hyperæmia of the cord, as pathological entities, they are entitled to no place in the nomenclature of traumatic spinal diseases.

5. Eccentric lesions of the back, without any implication of the cord, may, nevertheless, by pressure on the meninges secondarily give rise to meningitis, local or general; also by infection, propagated inward, ultimately effect the medulla-spinalis. Those extrinsic injuries may, too, of themselves, by inducing pathological changes in the bones, cartilages, joints or muscles, occasion a permanent weakening or loss of power in the back.

6. It should be constantly borne in mind that there are always essentially two different and distinct sets of pathological lesions which result from spinal injury, viz., those involving the cord, of rare occurrence and generally fatal, and those exterior to the spinal canal, very common, but seldom giving rise to serious impediment of function.

THERE are in the United States and Canada forty-seven medical faculties which admit students of both sexes, and nine for women only.

ELECTRO-DIAGNOSIS IN BRAIN AND NERVE INJURIES—METHODS USED AND THE APPARATUS REQUIRED.

Read before the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY W. H. WALLING, M.D.,

OF PHILADELPHIA, PA.

There are two very important propositions to be considered in connection with electro-diagnosis, the first of which is, an adequate knowledge of electro-physics and electro-physiology, and the second, the need of the proper apparatus with which to conduct such investigation.

The first proposition, or a proper understanding of the subjects named, is so obviously essential that it is scarcely necessary to discuss it.

The apparatus required for accurate electro-diagnosis merits our careful consideration. While with an ordinary faradic battery and common electrodes the approximate condition of a nerve may be arrived at, our tests will be of only a proportionate value.

The batteries, meter and controller that I use here to-day were made by Mr. Otto Fleming, of Philadelphia.

Unfortunately, we have no definite standard in this country for our faradic coils, or for the size of our electrodes, hence the resulting confusion in comparative tests by different operators. It is to be hoped that the American Electro-Therapeutic Association will, at its next meeting, appoint a committee to consider this very important question of the standardization of our apparatus and electrodes. This is secondary in importance only to the proper standardization of the fluid extracts and tinctures of the U. S. P., which I so strenuously advocate.

For electro-diagnosis three different currents are used, the faradic, the galvanic, and the franklinic. The faradic coil, which I use in diagnosis, which I here show you, is constructed upon the DuBois-Reymond principle, and graduated, by means of a scale, into centimeters and millimeters. The cell used to operate this coil is a modification of a grenet cell, and has an electro-motive force of one and a half volts. For my stationary coil I use two modified Law cells, as they are less troublesome, and are quite constant in action. The dry cells have not, as yet, met our expectations, when used upon the faradic coil. It must be remembered that the cell, in all faradic machines, is on what is termed short circuit when in use, hence the dry cell, having a tendency to rapidly polarize, soon runs down, and the battery will not work until the cell has time to recover.

This apparatus is supplied with a slow, as well as a rapid interrupter, and the movements of the former may be regulated to suit the operator.

With a machine constructed upon this plan, the exact coil distance required to produce a contraction, if one be obtainable, may be observed and recorded, and active comparisons made from time to time.

It has been repeatedly stated that it makes no difference which of the two poles of the faradic battery are used, as the reaction of nerve and muscle is the same for both poles. I dissent from this statement. In testing a nerve with my office coil, for instance, I find that I can get a contraction with the cathode from six and a half centimeters coil distance, while seven and a half centimeters are required with the anode to get the same contraction. This from the primary coil. With the secondary coil the same contraction was produced by two centimeters c.d., cathodal closure, and two and eight-tenths of c.d. were required with the anode.

The electrodes selected to make the first examination should be used throughout the case. Erb recommends that the active electrode should be ten square centimeters surface measure; Stintzing one of three centimeters surface. Erb's instrument is the one most generally used. Both electrodes should be covered in the same manner, preferably with absorbent cotton, wetted to the same degree, in the same solution, and be placed upon the same spots on the body at each examination, and the pressure should also be the same as near as possible.

The size of the electrodes used make a vast difference in the amount of current required in order to produce a contraction.

For the purpose of general diagnosis, the patient is prepared by removing as much of the clothing as may be necessary, and, if a female, protected by a sheet or loose wrapper, and seated upon a suitable stool, upon which a wet sponge electrode is placed, attached to the positive pole of the secondary coil of a faradic machine. The operator then takes a small, well-wetted sponge or cotton-covered electrode, attached to the negative pole, and, commencing at the nape of the neck, with a current plainly perceptible to the patient, passes down the back upon both sides of the spinal column, noting the effect produced. If there are tender spots, they will be quickly apparent by the patient wincing, or saying that it is painful. Note the coil distance required to locate these spots. Anæsthesia may be present in some areas, and more current be necessary to produce an impression.

The tender spots indicate points of greater or less inflammation. Blood being the best conductor of all the tissues of the body, all such foci of congestion or inflammation offer less resistance to the current, consequently the greater amount will seek to pass in that direction, and cause the pain by reason of such density. Test both sides of the spinal column, and note all the reactions.

Pain is not always an indication of an inflammatory condition, or of a lesion, as when the sponge is passed around the sides of the patient, and over the ribs, more or less pain will be experienced, due to the effect of the vibrations upon the periosteum. This effect is always seen when the faradic current is used over bones which are superficial, such as the scapula, etc. As the electrode passes over the motor points of some of the abdominal muscles, they will be strongly contracted, but this is, as a rule, of no particular significance. For testing for anæsthesia, this small electrode will be found useful; also for testing the electro-cutaneous sensibility of various parts of the skin. It is made of a large number of copper wires, closely approximated, but insulated from each other, and placed in this hard-rubber case. The coil distance necessary to produce a sensation upon different parts may be compared. This electrode is to be attached to one pole of the secondary coil, and the other placed upon the sternum, and the coil distance required to produce a sensation noted. A painful impression is then given, and noted, when the active electrode is removed to the opposite side of the body, and the same test made, when the two may be compared.

Diminution of sensibility, or sensory irritability, is present in nearly all lesions of the spinal cord and peripheral nerves, which are serious in character, and is also present in many cerebral affections.

Stintzing has tabulated the normal reactions of nerves to the faradic current, a few examples of which I present. The numbers are the millimeters on scale:

Musculo cutaneous, contraction at 15 m.m.

Frontal branch of facial, 25 m.m.

Ulnar, at olecranon, 31.5 m.m.

Crural, 38.5 m.m.

Radial, 45 m.m.

As no two machines are alike, the value of these tables are only approximate.

THE GALVANIC BATTERY.

As the galvanic battery is our sheet anchor in definite electro-diagnosis, it is essential that everything be as perfect and complete as possible. The battery must be able to maintain a fairly constant potential, and for this purpose, especially for an office, or stationary battery, the Law or Leclanche cells are the best. The cells should be coupled in series; that is, the zinc of the first cell is attached to the carbon of the second, the zinc of the second to the carbon of the third, and so on until all are connected, the battery consisting of from forty to eighty or more cells. The two terminal wires from the end cells are run to the controller and meter, thus completing the circuit. This is the common arrangement, but I prefer to have each cell connected

with my switch-board, so that I may select any number, from one up to the whole number. My reasons for such arrangement are, that where you are using the whole battery, and attempt to control the current by means of the rheostat, the ampérage is alone controlled, and not the voltage. In this connection, I desire to enter my protest against the use of the Edison electric-light current for medical purposes. It will charge your secondary batteries, light your houses, your streets, and some of the cavities of the body, but I consider it unsafe and unreliable when used in place of a chemical galvanic battery. There is too much voltage, or electro-motive force, which cannot be properly controlled. But there is the greater danger of a short circuit somewhere, and of the whole current being thrown in upon an unsuspecting patient, with damage to health, and possible loss of life. Such accidents have happened, and are liable at any moment to be repeated.

It is also on account of the high voltage from the primary battery, when all the cells are constantly in circuit, that I object to the series arrangement. Suppose, for instance, that you wish to use one-half of a milliampère of current upon the eye; of what possible use have you for eighty to a hundred volts of pressure? Not only is such pressure useless, but it is hurtful, if not positively damaging. This I have demonstrated again and again, to my entire satisfaction. For instance, one of a series of patients referred to me by Prof. Keyser for treatment for facial paralysis, and now under my care, complains of intense pain in the supra-orbital nerve, with only one-half of a ma. of current, when I have fifty cells in circuit, the current-controller being also used, but bears one ma. from twenty cells, not only without pain, but with positive comfort. A painful and sensitive nerve quickly differentiates against voltage. It seems evident that as we throw in resistance, by means of a rheostat, we increase the pressure, and my rule is to use only just a sufficient number of cells to give the current strength I want, and no more. All above that number is a waste of force, and a positive disadvantage.

When making a diagnosis, the meter, but not the controller, should be in the circuit. DeWattville's method is to place the electrodes in position, and commence with ten cells, adding cell by cell as needed, to get the reaction desired. I have tried various methods, but have gone back to DeWattville's plan, as being the most satisfactory. For brain testing I have a separate series of ten cells, arranged according to my plan, and kept most exclusively for the purpose named.

Attention to polarity was seen to be of advantage, when using the faradic battery. With the galvanic, polarity becomes of prime importance, for the reaction of nerves is distinctive for each

pole, and gives definite and unvarying results, when intelligently applied. Suppose that we wish to test the median nerves, in its most superficial portion, about two inches above the annular ligament. With the anode, or positive pole, placed on some convenient point, place this small electrode, attached to the cathode, or negative pole, upon the nerve, and turn on the current. So long as there is no break in the current, there is no movement of the muscle, differing in this respect from the faradic current. Having say two or three ma. the current is broken, and again suddenly closed. A quick, sharp, lightning-like contraction of a healthy muscle takes place, quickly subsiding. Upon reversing the polarity of the battery, we will find that it requires more current to get the same contraction with the anode, than it did with the cathode. Upon this has been based the following formula of normal reactions of nerve and muscles.

First we have cathodal closing contraction, c. c. c.

Followed by anodal closing contraction, a. c. c. and this

Followed by anodal opening contraction, a. o. c.

The two latter may change places and still be classed as normal, but if the anodal closing contraction appears first, we then have what is termed the reaction of degeneration, generally expressed by the letters, R. D.

There is a fourth reaction, the cathodal opening contraction, but it requires too strong a current to produce it, and being painful, I do not attempt it in health. Ordinarily, we will get the three contractions above noted with about the following current strength, that is in healthy subjects:

Cathodal closing contraction, with 2 to 5 milliampères.

Anodal closing contraction, with 5 to 8 milliampères.

Anodal opening contraction, with 5 to 8 milliampères.

These numbers are only approximate, as much depends upon the condition of the subject, whether there be much or little adipose tissue to deal with.

To illustrate the reactions, we will take a case of injury to the arm, the result, we will say, of a railway accident. The patient states that the arm has been rendered useless. Having bared both arms, and the chest of the patient, place a large, well wetted sponge, or other electrode, upon the sternum, connected with the positive pole of the faradic battery, and with the small negative electrode, test the well arm first, noting the coil distance necessary to produce a contraction. Use the secondary coil in such testing. Next test the diseased arm, noting, as Bramwell tersely puts it:

"1. Whether a muscular contraction is produced or not.

2. If a contraction is produced, what is the minimum strength of current required to produce it, and whether the character of the contraction is in any way altered from the normal.

3. The strength of current and the rapidity (whether slow or quick) of the interruptions required to produce the maximum amount of muscular contraction." It is better, in all such cases, to test corresponding groups of muscles, as above stated, so as to compare results.

Next test with galvanic current and note

"1. Whether a muscular contraction is produced or not.

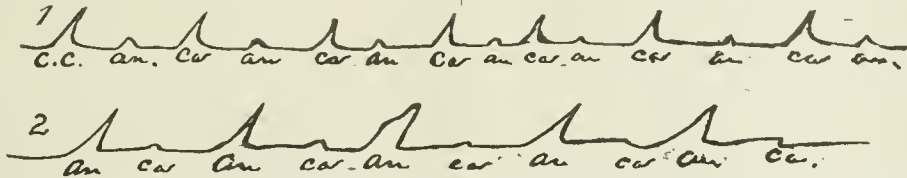

2. If a contraction is produced [*a*] what is the minimum strength of current required to produce it; [*b*] the order of the polar reactions; [*c*] the character of the contractions, whether healthy or not; [*d*] the strength of current required to produce tetanus; [*e*] whether the con-

tractions are more easily excited by slow or quick interruptions of the current."

In order to get the most satisfactory reactions, the muscles must be relaxed. If you get conflicting or confusing reactions, and the patient is resisting the current, he must be placed under ether, or some other anæsthetic, when the proper reactions will readily appear.

If, however, you find the normal formula reversed, that is, if anodal closing contraction comes before cathodal closing contraction, you may be assured that there is degeneration, as the reactions of degeneration cannot be simulated.

We are here dealing with a peripheral paralysis, and the reaction of degeneration appears, because the nerve has been separated from its trophic center in the cord. I herewith present a graphic representation of the normal reaction of a nerve under galvanic stimulation.

The first shows the normal reaction, with a quick sharp contraction of the cathodal closing, while the second shows the reversal of the formula, with the anodal closing contraction appearing first, which is the reaction of degeneration.

The following table, taken from Dr. Adams' little work, and compiled from Erb, shows the relationship between the reaction of degeneration,

and the histological changes accompanying it, this "reaction of degeneration depending upon a specific histological modification of the irritable tissues, called 'degenerative atrophy,' and this degeneration itself is due to an interference with, or a stoppage of, the peculiar influence of the gray matter upon the nerves and muscles, known as 'trophic' influence."

Seat of Lesion.	Prominent Symptoms.	Electrical Reactions.	Pathological Conditions and Their Location.
Path of impulse from the brain (antero-lateral columns); or the brain itself.	Paralysis. No muscular degeneration.	All normal.	Lateral sclerosis (idiopathic or from cerebral disease).
"Trophic centre" for the muscle, and also the path of impulse from the brain (antero-lateral columns).	Paralysis. Muscular degeneration.	Nerve: Normal. Muscle: Qualitative and quantitative alterations. (Partial R. D.)	Amytrophic lateral sclerosis.
"Trophic centre" extending to multipolar ganglion cell of the anterior horn of gray matter.	No paralysis at first. Muscular (afterwards nervous) degeneration.	Nerve: At first normal; afterwards diminished. Muscle: Qualitative and quantitative alterations. (Partial R. D.)	Progressive muscular atrophy (of central origin). Bulbar paralysis. Mild acute poliomyelitis.
Multipolar ganglion cell of the anterior horn of gray matter.	Paralysis. Atrophy of muscles and nerves. Abolition of reflex actions.	Nerve: Reaction of. Muscle: Degeneration.	Anterior poliomyelitis. Infantile paralysis. Lead poisoning.
Motor nerve-fibre.	Paralysis. No degeneration.	All normal.	Light form of rheumatic, traumatic, or pressure paralysis.
Motor nerve fibre and path of trophic influence to muscle.	Paralysis. Muscular degeneration.	Nerve: Normal. Muscle: Qualitative and quantitative alterations. (Partial R. D.)	Middle form of ditto.
Motor nerve-fibre, path of trophic influence to muscle, and path of same to nerve.	Paralysis. Muscular and nervous degeneration.	Nerve: Reaction of. Muscle: Degeneration.	Severe form of ditto.
Muscular fibre.	Pseudo-paralysis. Simple atrophy.	Normal, or diminution to maximum excitation.	Muscular wasting in phthisis, etc., and in diseases of the joints. Idiopathic myositis.

There is another and important factor to be considered in all these cases, and that is the resistance of the patient. When a galvanic current is passed through the tissues of the body, it meets with resistance, differing with the portion traversed. The dry epidermis offers the greatest resistance, presenting, according to some observers, as high as three hundred times as great a resistance as that of all the intervening tissues, when a current is passed by percutaneous application, with two layers of the epidermis intervening.

This resistance may so vary upon different sides of the body, as to be very misleading, unless carefully considered. For instance, if, in testing an arm for a supposed lesion, you found that it required a much stronger current to produce a contraction upon one side than upon the other, before diagnosing the injury, test the resistance of the two sides, and you may find the difficulty there. This testing is done by means of resistance coils, which should be attached to every office battery, and range in power up to at least 20,000 ohms.

Still another point in this connection is, that as the current passes through the body, the resistance more or less rapidly declines, due to two causes: the moistening of the dry epidermis, and, according to Prof. Rhoe, the electrolytic arrangement of the molecules in the track of the current. Both have their influence.

In some conditions, I have found cocaine cataphoresis to be of great value in determining whether a lesion was superficial or not. For instance, in a case of severe tic, if cocaine be used upon the anode, and applied to the nerve, and relief be not obtained, the lesion is deeply seated. If, on the contrary, the pain is controlled, the lesion is superficial, and an operation is not, as a rule, indicated.

[Dr. Starr, and Dr. Peterson, of New York, have done much in this direction, especially the latter.]

In testing nerve and muscle, also during treatment, I have noticed some curious phenomena. A case under my care, in which the hand had been amputated, gave, upon tests, and frequently during treatment, sensations of contraction of the muscles of the amputated hand, and the patient complained that the hand pained him, at such times.

BRAIN AND SPINAL CORD LESIONS.

In brain testing, the phenomena are mostly subjective, and yet, as the patient, unless familiar with the reactions, not knowing what to expect, will generally give correct descriptions of what is taking place.

We will take a normal brain, and note some of the reactions produced by the galvanic current,

first noting that there are the following methods of brain galvanization: longitudinal, transverse and oblique. The transverse is subdivided into bitemporal, from the parietal prominences, the mastoid processes, and suboccipital. In a normal, healthy brain, no unpleasant sensations are felt, more than a possible slight dizziness, when a current of from 3, or even 5, and in some instances more, ma. are passed through it, in any direction. By reversing the current, without shock (which should always be avoided), the molecular arrangement having been disturbed, the sensation of dizziness will most likely be produced.

In anæmia, the tissues being but poorly supplied with blood, the reactions might not appear, but pain would follow. In hyperæmia, however, the effect is very marked, and I have had patients almost fall from the chair, when only a very mild current was applied. In cases of brain tumors, the patients complained of great pain in the region of the tumors, when the electrodes rested over it.

The optic nerve is stimulated by both the galvanic and faradic current. The former, however, is the one to use in such testing. When a feeble current is broken or made, with the electrodes placed transversely upon the temples and in other directions, the optic nerve will be stimulated, and a flash of light be noticed. In some cases of paralysis of the orbicularis palpebrarum, I have noticed that this stimulation was very marked in the affected eye, in cases of central lesion. Where the cause was peripheral, the lesion was not particularly marked. In a case of almost complete loss of vision in one eye, the result of a syphilitic iritis, the optic nerve on that side will not respond to any current which I would use upon the head. In the case of a gentleman now under my care, with beginning sclerosis of the brain, I find that at times, especially after prolonged mental exertion, he can bear but a very mild current through the mastoid region, say $1\frac{1}{2}$ ma., or longitudinally, without considerable pain being experienced. He is subject to sudden attacks of epistaxis, which afford more or less relief. Now while this patient cannot bear the moderate currents alluded to, when comparatively small electrodes are used, yet with a positive helmet covering the entire head, 20 ma. may be given with comfort and benefit, the negative being at the feet.

The use of the static spark in diagnosis, is at times essential. When a nerve will not respond to either the galvanic or faradic current, it will sometimes do so to the static spark, thus showing a continuity, not otherwise demonstrated. The reason for this is, that the franklinic current possesses such an enormous voltage, which penetrates deeply, affecting areas that the other currents fail to sufficiently stimulate. Obviously this current is not available for use about the

head, in diagnosis, but must be confined to the trunk or limbs.

The reactions of the auditory nerve to the galvanic current, as formulated by Brenner, are painful to produce, and few patients will be found, who are willing to submit to them. I seldom attempt them. In some cases of tinnitus aurium, the tinnitus will subside entirely during the passage of a mild current through the auditory nerve, and in such patients I give a very favorable prognosis.

The effect of the electric current upon sensory nerves differs from that upon motor nerves, in that the sensory nerves are stimulated by a continuous flow of either current. With the galvanic, a sensation is felt with a weaker current with ca. cl., an. cl., and an. o., than with a continuous flow, in this respect behaving precisely as do the motor nerves.

RECAPITULATION.

When a lesion is in the cord, above the dorso-enlargement, as in some forms of transverse myelitis, all the nerve and muscle reactions will be normal, for the parts below the trophic centre, except that possibly there may be some increase in readiness of response to electro-stimulation. If the lesion involves the dorso-enlargement, of course there would be the reactions of degeneration.

If the lesion be in the basal ganglia, or in the hemispheres above, there will be no change in the normal formula, unless the disease, in its progress, produces changes in the cord, thus affecting peripheral nerves.

In a hemiplegia, the result of a clot in the corpus striatum, there will be no change in the reactions, except that in some cases, the muscles respond more readily than the normal muscles, to both currents. In other cases, the reactions are simply normal, but in still other cases, there may be a quantitative decline, due merely to the degenerative changes in nerve and muscle.

In uncomplicated lateral sclerosis, the reactions are all normal. I have a case of lateral sclerosis under my care, of eight years standing, and specific in origin, which, when first tested, some six months ago, showed partial reaction of degeneration, but now the normal formula has been re-established.

In amyotrophic lateral sclerosis, there will be both qualitative and quantitative changes in the muscles, or partial reaction of degeneration.

In anterior poliomyelitis, infantile paralysis, and in lead palsy, we have the reaction of degeneration.

It will also be found in peripheral paralysis of traumatic, rheumatic, neuritic or diphtheritic origin. It is absent in all cerebral, hysterical, myelitic and purely myopathic paralyses.

In cases where the reaction of degeneration is

limited to a definite peripheral neuro-muscular area, the probabilities are in favor of the diagnosis of a peripheral lesion. When the phenomena of R. D. are observed over a larger area, a central (spinal) origin of the paralysis is rendered probable.

In light forms of rheumatic, traumatic, or pressure paralysis, the reactions will all be normal. In the middle form of these affections, qualitative and quantitative changes appear, and there is partial reaction of degeneration. When the severe form appears, we then have complete reaction of degeneration, or the normal formula completely reversed.

In muscular wasting, or simple atrophy, such as in phthisis, etc.; in diseases of the joints, and in idiopathic myositis, the reactions are normal, or the diminution is to the maximum of excitation.

By quantitative changes, is meant an increase, a diminution, or a total disappearance of electrical irritability to one or both currents.

By qualitative changes, are meant a modification in kind, of the normal reactions of nerve and muscle, to electric currents. This is the so-called "reaction of degeneration."

There is a third, or a mixed change, or a combination of quantitative and qualitative variations of irritability.¹

The histological changes shown in the preceding table, explains the phenomena of the reaction of degeneration. There is a solution of continuity, and a consequent inability to transmit impressions. Gessler, in his researches upon cold-blooded animals, seemed to prove that true R. D. was entirely due to muscular degeneration, as, while in these animals complete nerve degeneration occurred, muscular degeneration as well as R. D. were absent.

There is much yet to be learned regarding brain diagnosis, and I hope at some future time to present the result of some investigations that I am making in this direction.

2005 Arch St., Philadelphia.

SOCIETY PROCEEDINGS.

Medico-Legal Society of Chicago.

Mr. President and Gentlemen of the Society: Instead of presenting the clinical symptoms of acute arsenical poisoning in the abstract, I have thought a brief description of the symptoms, as observed by myself and others in a series of cases, would be more profitable, and, perhaps, more interesting. By the kindness of Dr. J. E. De Wolf, of Englewood, Dr. Chas. J. Simons and Dr. J. S. Knox, I am able to present the following series of cases:

¹ Bibliography: Liebig and Rohé, Ranney, Adams, Cleavinger, Erb, De Wetteville, Bartholow.

THE CLINICAL ASPECTS OF ACUTE ARSENICAL POISONING.

Presented before the Medico-Legal Society of Chicago, Oct. 3, 1891.

By DANIEL T. NELSON, M.D., of Chicago.

The Newland cases you are familiar with in a general way, where the servant girl poisoned an entire family in Englewood. Dr. De Wolf writes me a few notes from memory, as follows:

I responded about 8 o'clock P.M., in April, 1890, to an order coming from the Newland family at about 7 P.M. The entire family, consisting of four members, were sick; the father and mother were in bed. The son, a young man who was out looking for help, soon came in, telling me he had been vomiting freely on the street, and he, too, was obliged to lie down. The daughter, a young lady, was able to be on her feet at this hour, and had not, I think, vomited, although feeling some discomfort in her stomach and bowels. The father and mother had been for half an hour, and still continued, vomiting freely, and complained of pains in the stomach and bowels, and also of dryness of the throat. They seemed not inclined, or not able, to give any explanation of their condition, but learning that they had all sat down together at supper at the usual hour (6 or 6:30) and in their usual happy mood, and finding them thus prostrated, I suspected poisoning, although I could not think it intentional, as it was the first meal prepared by a newly arrived domestic; but learning that she had not eaten with the family, and was missing from the house, added to my fears. Before these facts could be gleaned some time had passed; emetics had been given, and emesis was followed by the free exhibition of demulcent liquids. The symptoms at this point were chiefly those of intense gastro enteritis, but superadded to these came some evidence of arsenical poisoning. In Mr. Newland's case the abdomen became swollen and tender, while the skin was pale and cold, with a clammy sweat, the pulse frequent, small and irregular, the respiration labored, with frequent cramping of the extremities. Mrs. Newland's case differed from that of her husband in that there was a hot and dry skin, with but little if any cramping of the limbs, and with some tendency to delirium, or at least to marked stupor. The other two members of the family presented the same symptoms, but in a less marked degree. In each case anodynes for the relief of pain were given, and the hydrated sesquioxide of iron was given as an antidote to the arsenical poisoning which was suspected.

Two hours after my arrival, Dr. D. T. Nelson was asked for his council, and agreed with me that there seemed to be no need of the stomach pump, as emesis had been so thoroughly effected.

Mr. Newman died about five o'clock of the following morning, and Mrs. Newman at noon of

the following day, while the others made a good recovery within a week.

The form of poison used was a kind of arsenical paste, which is called "Rough on Rats," that the servant procured from a neighboring drug store. According to her statement, she put it into the corn, probably after it was cooked. I think no remains of the package could be found. The corn, as I recollect it, was the only dish that was partaken of by all of the family.

From Dr. Simons I was fortunately able to gather a series of cases.

Case 1.—A girl, 18 years old, on account of a love affair, attempted to commit suicide by taking Fowler's solution at bedtime. Dr. Simons saw her within an hour. There were some cramps in the abdomen, with thirst and dryness of the throat. There was purging (but he thinks not from the emetic, which was tartarized antimony) and bloody stools. Hydrate sesquioxide of iron was given as an antidote after the vomiting. She recovered after a week's illness. There was no paralysis.

Case 2.—A family named Fritz; the man was a laborer. There were five in the family, father, mother, and three children from three to ten years old. White arsenic was taken in coffee. They lived in a house by themselves. The family was seen about the house as usual in the evening, and the next morning they did not show any signs of life. The neighbors became alarmed about seven or eight o'clock in the morning, and began to investigate, and found the family all sick. They lived near 18th and Arnold streets, where the County Hospital was then located. Dr. Pitcher, who was county physician at that time, was summoned, but he was not at home, and Dr. Simons was called in. He reached the family about 9 o'clock in the morning, and they were supposed to have taken the poisoned coffee about bedtime, or in the early night, so that it was about twelve hours after taking the poison before the event was known. The mother and two children were dead, but the father and youngest child were still alive. Here arises an interesting question: Why was the father and the babe, which was about three years old, alive? Was it because they had taken a less quantity, or vomited more, or were stronger to resist the poison? The father was not a drinking man. He vomited arsenic, and arsenic was found in his stomach and that of all the others. He was taken as soon as possible to the County Hospital, and his stomach washed out with a pump. He lived two hours. The baby died within two or three hours. When Dr. Simons reached the house, about 9 o'clock, the father was unconscious, but he became conscious before he died. He would not tell who gave him the poison, whether the mother gave it to the whole family, or whether there was an agree-

ment between the father and mother; no one ever found out what arrangement was made. The father had severe diarrhœa and cramps, and suffered greatly. The child vomited without an emetic, and also had severe diarrhœa and cramps. No antidote was given because it could not be swallowed.

Case 3.—A servant girl 23 years old. She had lived with this family some five or six weeks and had always seemed peculiar. She ate Paris green or Scheele's green. She stirred it up with water and drank it, smearing her mouth, her face, her hands, the cup in which she mixed it and the shelf on which it lay. The vomited matter showed what the substance was. Dr. Simons was called in about fifteen minutes after she took it and gave her an emetic; she had vomited previously from the arsenic. There was purging but no cramps. In an hour or two she was taken to Michael Reese Hospital and the subsequent history is not known. She vomited freely the eggs and other demulcents which had been given to her. The stomach was washed out in the hospital but no antidote was given.

Dr. Knox writes me as follows: In 1872, while suffering from neuralgia of the heart, I took through the error of the druggist, one dose of two teaspoonfuls of Fowler's solution, equal to one grain of arsenious acid. About two hours afterwards I had constriction of the fauces, intense burning pain of the stomach, severe colicky pains in the bowels, and subsequently vomiting and dysenteric diarrhœa.

The cause of the poisoning was suspected and I was promptly treated with tablespoonful doses of moist hydrated sesquioxide of iron every fifteen minutes. There was relief in a few hours and no subsequent ill results.

The symptoms as you gather them up, of cold sweats, pinched appearance of the countenance, cold, clammy extremities, and small, rapid pulse are perhaps as marked a series of symptoms as we have, and yet it might be questioned whether these were entirely and positively pathognomonic. Some of these symptoms we get in corrosive sublimate poisoning; the severe bloody vomiting and cramps. You do not get so much, perhaps, of the colicky pains in the bowels, you do not perhaps get such very marked evidence of shock, and yet you will see it. In the only case I have seen of corrosive sublimate poisoning there was quite marked evidence of shock.

Perhaps it will be no credit to myself if I say that I supposed I was poisoned by arsenic while in college. I was working over some small test tubes with the blowpipe, blowing them out with my mouth, and I supposed I had taken some arsenic into my mouth and throat. Not knowing exactly how much it took to produce poisonous effects, I became frightened. I grew pale, had a rapid pulse and thought I had pains in my

stomach and bowels, but did not vomit. I was getting ready to take some antidote when my classmate suggested that perhaps it was not arsenic, that he was working with zinc and he thought I was. I soon recovered when I found it was zinc.

The only other case I know of personally was chronic poisoning in which there was extreme weakness amounting almost to paralysis. At first there was ability to walk for months, finally ability to walk with two canes, gradually with one and then without any. It was the case of a celebrated Boston physician, whose name you are doubtless familiar with, Dr. Bumstead, a man who has been celebrated for years as an author of venereal diseases. He was poisoned apparently by arsenic, as he supposed from wall paper.

Perhaps I need not speak of some very self-evident things, that Fowler's solution is perhaps the worst form of the poison to take; being in solution it is rapidly absorbed and not easily thrown off by emetics or otherwise, or reached by antidotes. In some regions it is a common domestic remedy, and known as the "ague drop," and is liable to be used as a poison accidentally, if not intentionally. Fortunately the odor of lavender gives it a specific and peculiar odor so that it may be detected, and if vomited the odor will lead the physician to suspect what he has to deal with.

Another question might be raised, and I suggest it for your discussion: Whether there is arsenic enough discharged from smelter chimneys to be of injury to persons, animals or foliage. You will sometimes notice from the smelter works at 40th street and Armour avenue, the peculiar sweet odor of arsenic. In looking over some books, I noticed that some one had prescribed Fowler's solution in two teaspoon doses for snake bite, and had been very successful in making the patient vomit. The doses were given every half hour until the patient was relieved. I was wondering which was most likely to kill, the snake bite or the remedy, but the patient is reported to have rapidly recovered, so we suspect the Fowler's solution was thrown off by the vomiting.

One of the patients you notice was said to be comatose; the question where the coma comes from is interesting. In some cases bloody albuminous urine is reported. Is the coma the effect of the poison on the kidneys? Is it uremic coma?

I did not intend this to be anything like a full presentation of "the clinical aspects," but I thought as I was able to gather together some of these cases, if I could get something of a series, it would be perhaps more interesting. I have not touched upon the treatment, as I thought that belonged to another department.

SPONTANEOUS RECOVERY IN ACUTE ARSENICAL POISONING.

Read before the Medico-Legal Society of Chicago, October 3, 1891.

By HAROLD N. MOYER, M.D.

Almost every poisonous substance is characterized by some fairly pathognomonic symptoms, with the exception of arsenic. It belongs to the class of intestinal irritants, the symptoms of which may be closely imitated by any simple inflammation of these parts. We lack the characteristic symptoms presented by opium, belladonna or strychnia, so that a certain diagnosis of arsenical poisoning is difficult or impossible without the aid of a chemical analysis. The symptoms and pathological appearances in acute arsenical poisoning are fairly constant, and yet there is an occasional case in which there is such a wide divergence from the typical picture that there is great liability to error. With these uncertainties clearly before us, we should be very careful in advancing a dogmatic opinion.

The average fatal dose of arsenic is well known, but the literature of medicine contains many cases where spontaneous recovery has taken place after the ingestion of a quantity many times greater than a dose that commonly proves fatal. It is apparent that the factors governing these cases are exceedingly various. The resistance of the patient may be greater than usual; a dose, granting that it is all absorbed, may be eliminated in one case, that in another would prove fatal. Again, the rate of absorption may vary. If the arsenical preparation is relatively insoluble, it may be so long in entering the circulation that the greater portion is either vomited, or passed off by the bowels in consequence of the violent peristalsis produced by the drug. As a matter of fact, it is only exceptional that recovery takes place when these violent symptoms are present. Recovery has, however, been noted after the taking of enormous quantities. Tidy refers most of these cases to that class in which the poison is taken upon a full stomach. As a consequence, the great bulk of the drug is rejected with the food in the first efforts at vomiting. It is probable that this is the explanation in most of the cases where spontaneous recovery has taken place after exceptionally large doses. It would be hazardous to deny the possibility of spontaneous recovery even when the arsenic has been administered upon an empty stomach, but we may at least say that it is highly improbable. Any one who has ever examined a stomach containing a considerable quantity of arsenic, must have noticed the closeness with which the powder adheres to the mucous lining of the organ. The healthy empty stomach always contains a small quantity of mucus, and this serves to glue the powder to the stomach walls, so that with violent vomiting it is gotten rid of with difficulty, or not at all.

The following case is one of peculiar interest, and is, so far as I know, the first time the question of spontaneous recovery from arsenic has been directly raised in a court of law.

The facts are briefly as follows: A man was charged with the attempted murder of his child, the motive alleged being a desire to inherit considerable property belonging to the latter. The testimony brought out at the trial showed that the child was $3\frac{1}{2}$ years of age, and that it had always been of delicate health. The night preceding the alleged poisoning, the child was taken vomiting shortly after eating a hearty supper. A physician was called in, and made a diagnosis of dyspepsia and bronchitis. The boy vomited once or twice during the night. At 15 or 30 minutes after 6 the following morning the father gave him a drink of water, in which it was supposed he had placed the poison. At 15 minutes after 7 a woman who had charge of the boy came into the room to dress him. He then complained of feeling ill and began to vomit. The nurse noticed that the tongue was covered with a thick green coat; the vomited matter was also mixed with a greenish substance that stained the towel upon which they were caught. A subsequent examination of these cloths showed the greenish matter to be Paris green, the quantity recovered amounting in all to about 2 grs. (Regarding the quantity of Paris green, there is a discrepancy between the testimony of the physicians who examined the towels and the chemist who made the tests. The former say that at least $\frac{1}{2}$ teaspoonful would be required to produce the amount of staining which they saw. We may disregard this, however, as the smallest quantity stated, 2 grs., is amply sufficient to cause death in a child $3\frac{1}{2}$ years old.) A servant also noted and testified that the child vomited a greenish substance. As soon as the vomiting began a physician was summoned, who reached the house at 8:15 A.M. On the strength of the statements made to him he prescribed an antidote and an emetic, the latter acting freely. This physician refused on the stand to state that he believed the symptoms were due to arsenical poisoning, as he thought they were too mild. A second physician, who saw the child at 10:30 the same morning, also refused to state that in his opinion the illness was caused by arsenical poisoning. After the effects of the emetics passed off, there was no special disturbance of the child's health, no vomiting, purging, inflammation or prostration.

Certain facts in the above account show that this case is one that must be classed among the spontaneous recoveries, granting that a fatal dose of arsenic had been administered as alleged. It must also be placed among the unusual ones, as the poison was given on an empty stomach. At least three-fourths of an hour elapsed from the

latest time when the poison could possibly have been administered before the child began to vomit, then he was given some milk and he vomited again. One hour later a physician arrived and administered an emetic, but at this time no greenish matters were discharged.

The question naturally presents itself, and it was one upon which we were asked for an opinion, "Was the Paris green administered as alleged?" If we assume that it was given, then we affirm the possibility of recovery upon an empty stomach, and without the use of antidote or emetic. Granting this possibility, the additional fact presents itself, in this case, that the child was not ill after this severe dose of arsenic. Assuming that the vomiting was caused by the poison, sufficient must have been absorbed to cause marked irritation of the stomach. Is this possible in view of the fact that there was no purging, inflammation or prostration three hours after the administration? Beck mentions a case of spontaneous recovery after Paris green poisoning in a young boy. Recovery took place only after a prolonged illness, with severe prostration. It is a general experience that recovery after acute arsenical poisoning, if sufficient time has elapsed for vomiting to have occurred from action of the drug, is exceedingly slow. The patient is often prostrated for days, and sometimes death takes place long after the administration of the fatal dose.

In view of the very great uncertainty that surrounds the subject of acute arsenical poisoning, we can hardly deny that arsenic was administered in this case, and yet a careful consideration of all the facts throws at least a reasonable doubt on the testimony. An opinion was accordingly given that, while the facts as brought out in the testimony were not inherently impossible, they were in a high degree exceptional.

A very ingenious explanation was offered by one of the medical witnesses. He would account for the spontaneous recovery on the theory that, as the child was suffering from bronchitis, it must have swallowed a considerable quantity of mucus during the night. This he thought would act in much the same way as a quantity of food in delaying absorption of the poison.

CHEMICAL CONSIDERATION IN POISONING.

Presented before the Medico-Legal Society of Chicago, Oct. 3, 1891.

By C. D. WESCOTT, M.D.

I am very sorry, as I know you all are, that Dr. Haines cannot be present to-night. From a little talk we had late last evening, I know that he would have contributed some very interesting matter, although he had been unable, from lack of time, to prepare a paper or even an abstract. However, he asked me to bring up one or two points which his experience has brought to mind.

One of these points has already been raised by Dr. Hektoen, that is, the fact that the embalming fluids in common use by undertakers often interfere with the detection and punishment of crime. Professor Haines has been engaged as chemical expert in at least five cases where there seemed to be abundant evidence of murder by arsenical poisoning, in which the fact of arsenical fluids having been used in embalming made it impossible to convict. And in another case, an innocent person came very near going to the penitentiary because of the accidental contamination of a stomach contents by arsenic from an embalming fluid. It may be well for me to recite the principal details of some of these cases.

In one case a man had made a will, bequeathing his wife a certain portion of his property; he determined to change the will, and in such a manner that she would be a hundred thousand dollars worse off; and so announced to her. There seemed to be abundant evidence to convict her of poisoning her husband with arsenic. Organs from the body of the man were submitted to Professor Haines for analysis and he found arsenic in the liver, stomach and contents of the stomach. And when these facts were brought before the woman and she was asked to plead guilty, she boasted that they would cut no figure, that she herself had ordered the undertaker to embalm the body and put all sorts of chemicals in it.

In another case, a maiden lady was found dead in the house of some people with whom she was living. It was learned that she had made a will bequeathing certain property to these people and that they had become aware that she intended to change the will to their disadvantage. Arsenical poisoning was suspected, and Professor Haines found in the stomach contents traces of arsenic. The stomach as an organ was not submitted. For some reason the body was re-examined and it was found that the stomach had been carefully washed out and that the abdominal cavity contained fluid; it was learned that the undertaker had been there in the meantime and put embalming fluid into the abdominal cavity, which upon examination was found to be arsenical. There was evidence to show that the people in the house had opened the body and washed out the stomach clean, still these people were not convicted of the crime because it could not be proven that the arsenic which Professor Haines had found in the stomach, was administered to the patient before death, because of the presence of the embalming fluid.

There is a very interesting chemical fact in connection with the other case in which an innocent party came near being punished. A woman suddenly died and somebody suspected that the husband had committed murder. There were some symptoms of arsenical poisoning, and the

stomach and other organs were submitted to Professor Haines for examination. A very small quantity of arsenic was found in the stomach contents, but Professor Haines had a feeling that it was not a case of arsenic poisoning, and he questioned the Doctor very carefully as to the possibility of any contamination of the stomach by arsenical fluid. The Doctor insisted that it was impossible. To make a long story short, it was found that the Doctor, when he removed the stomach contents, had asked the undertaker at whose place the body lay, for some sort of jar to put these contents into. The undertaker gave him a jar which he said had contained sulphate of zinc and nothing else; it was washed in a dark room several times with running water and was supposed to be clean. But it was afterwards ascertained that after the jar had been emptied of sulphate of zinc some arsenical embalming fluid remained in it for a short time. The interesting chemical fact in this connection is that although this jar had been thoroughly washed with water it did contain a little arsenic which had contaminated the contents of the stomach. To demonstrate how this was possible, Professor Haines experimented by securing some of the undertaker's embalming fluid and allowing it to stand a short time in a jar, when the characteristic crystal of arsenious oxide gathered around the sides. The fluid was poured off and it was shown that water could be repeatedly poured in and out of the jar without dislodging the arsenic.

As has already been mentioned this evening, there should be some legislation in regard to this matter of embalming fluids. Arsenical fluids are not necessary, in fact it is not necessary to embalm bodies with any substance which is a common poison, or which occurs commonly in suicidal cases or in murders. A mixture of alcohol, glycerine and water has long been used at Rush Medical College for preserving bodies for the purpose of dissection, and it has been found very efficient. Very few people suicide with alcohol, and no one has been murdered with alcohol to my knowledge; such a fluid therefore would not interfere with the detection of crime. If salicylic acid were added to this mixture, it would be even more effective and no less desirable as an embalming fluid.

Another point which Professor Haines suggested is that there is no absolute test for arsenic, that is no single test, and I personally know that Prof. Haines never testifies against a man accused of murder by arsenic without testing and retesting by the various established methods, and told me last night that now he never makes an examination in a case of poisoning without at the same time carrying on a blank test, even going so far as to use an organ from a recently killed animal or from a deadhouse, such as he is examining for poison. It is not enough that he

uses chemicals which he is sure are absolutely pure, it is not enough that he keeps those chemicals constantly under seal in his laboratory, but even though he is sure he has pure chemicals and clean utensils, he makes these parallel tests in all cases. This illustrates the fact spoken of by Dr. Hektoen, that only the most careful and competent persons should be entrusted with such examinations. Only men of such care and skill and conscience should give such evidence in such cases. It should be illegal to use any poisonous embalming fluid, and I hope this Society will take some action in regard to the matter with a view to securing legislation on this point.

Another point I would suggest is, that in spite of the great number of cases of arsenical poisoning, it is a wonder there are not more, because of the universal distribution of arsenic in a great many forms and the ease with which it can be obtained. The common flypaper used in so many houses, the black paper placed in dishes of water, is impregnated with arsenic, and cases of poisoning have occasionally been reported of children drinking this water.

(To be concluded.)

THE MORPHOLOGY OF BREAST MILK AND THE NUTRITION OF THE CHILD.—(Ivanoff. Thèse de Saint Petersburg, 1890.) An extensive study of this subject leads the author to the following conclusions:

1. The cellules of colostrum are of epithelial origin.
2. In multiparæ colostrum changes to milk more rapidly than in primiparæ.
3. Puerperal diseases retard the disappearance of the colostrum corpuscles.
4. These corpuscles reappear in the milk after ten months of lactation, and when the infant is only partly fed from the breast.
5. The free hyaline corpuscles, as well as those which are enclosed in the fatty globules, form a constituent of normal milk at a certain period of secretion.
6. Good health, good nutrition, and youth in the mother give a milk richest in fatty globules of large size, as is also true of the cellules.
7. The last portion of milk taken at a feeding holds fewer globules, and these of smaller size, than the first portions.
8. The estimation of the nutritive quality of milk should be based upon the number of fatty globules; and secondarily upon their size, the quantity of cellular element, and, finally, upon the quantity of granules.
9. Milk which contains a very large number of fatty globules (more than $3\frac{1}{2}$ per cent.) is not well borne by very young infants.
10. Milk, the globules of which are large, is less nutritive and less well borne.
11. The maximum of daily increase of weight of the child is produced by milk which contains a mean quantity of fatty globules of medium size (27.7 grams daily).
12. The milk which contains few fatty globules gives little increase of weight (16 grams daily); and the same is true if the fatty globules are in too great quantity or are too large (19 grams daily).
13. Women who are thin and young in general are the poorest nurses, often making the children dyspeptic and giving them a mean daily increase of weight of only 11.5 grams.—*Annals of Gynecology and Pædiatry.*

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,

NO. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, NOVEMBER 14, 1891.

THE GASTRIC JUICE IN BRIGHT'S DISEASE.

BIERNATSKI has recently investigated the gastric juice in Bright's disease, by the modern methods of research, and reported his results in *Vratch* (1891, Nos. 12, 18, and 21), of which *La Province Médicale*, October 10, 1891, gives an abstract. He selected twenty-five cases of Bright's disease, uncomplicated by disease of other organs, and particularly those cases which had not presented any digestive troubles, and which were not ascitic. The cases were all in the earlier stages, oliguria and œdema having been present only one, two or three weeks, and in age were between 25 and 40, with a few over 50. He gave trial meals, and determined the HCL qualitatively by the GUNZBERG test, and quantitatively by the SJOEQUIST method. The biuret reaction was used for peptones, UFFELMANN'S test for lactic acid, and the total acidity determined by decinormal solution of soda. The peptic power was determined by artificial digestion of albumen cubes, and the lab-ferment and lab-zymogen investigated by the methods of KLEMPERER and BOAS.

From this it will be seen that his methods were sufficiently complete to make his results valuable.

From his observations this general result was obtained: *The intensity and duration of the gastric secretion are diminished in nephritis.*

There were always great variations in the quantity of free hydrochloric acid, which was more or less diminished or entirely absent. After the EWALD trial meal the free HCL was rarely more than 0.02 per cent. to 0.04 per cent. The total acidity, however, was frequently above normal, notwithstanding the diminished amount of HCL. While peptonization always occurred, it was always slow or incomplete, notwithstanding the addition of free hydrochloric acid to the gastric juice. The lab-ferment and lab-zymogen were always deficient, and lactic acid was never present in large quantities.

The quantity of free HCL present is usually, if not always, below normal, but it is subject to great variations. A very direct relation seems to exist between the renal secretion, and the secretion of hydrochloric acid. Oliguria and œdema diminish the secretion of hydrochloric acid. In acute nephritis the secretion of hydrochloric acid very quickly returns to normal when the renal symptoms disappear, but in chronic nephritis the acid secretion does not reach a normal amount as long as there is albumen in the urine, even after the disappearance of œdema and oliguria.

In general, it was found that the longer the disease had continued, the more marked was the disturbance of the gastric secretion. The influence of uræmia was studied only in mild cases, and these showed a diminution in the hydrochloric acid secretion, greater than could be accounted for by the oliguria or œdema present, or by the duration of the disease.

From the foregoing, it may be inferred that a diminution in the secretion of hydrochloric acid occurs in renal incompetence, and is proportioned to the degree of the renal incompetence.

It is to be regretted that BIERNATSKI did not determine the relation of hydrochloric acid secretion to urea excretion, and thus bring his work into closer relation with that of DR. BOND, of Richmond, Ind.

It was found that the secretion of pepsin did not bear as direct a relation to the variations in the renal disorder as did the secretion of hydrochloric acid. In general it was found that the complete absence of pepsin is more frequent in nephritis, either acute or chronic, than the complete absence of free hydrochloric acid. This last observation is particularly valuable when it

is borne in mind that direct investigation of the stomach contents has shown that in the great majority of primary dyspepsias, the peptic strength of the gastric juice is not impaired.

Notwithstanding the diminished amount of gastric secretion, very slight evidences were found of any abnormal fermentations occurring in the stomach, which is due, according to the author, to the unimpaired mobility of the stomach.

The causes of the gastric disorders in nephritis are certainly complex, but it is probable, as the author suggests, that one of the factors concerned is the depressing effects upon the gastric mucosa of the waste products which have failed of elimination by the kidneys. Under these circumstances the gastric mucous membranes may possibly assume an excretory rôle. Poisons passed in this way, which would at first cause functional disturbances, would in time lead to the production of anatomical lesions, particularly atrophy and fatty or amyloid degeneration of the mucosa.

The changed chemical composition of the blood is no doubt another factor in the modification of the gastric secretion. BIERNATSKI attributes the origin of pepsin to the albumen of the blood, and holds the hypo-albuminosis of this fluid responsible for the diminished secretion of pepsin. This latter statement can hardly be accepted without great reservations.

By way of treatment the author suggests the use of peptonized milk, and the administration of lime salts, because of the absence of fermentation. Hydrochloric acid lemonade diminishes the unpleasant sensations of the patients, and at the same time regulates the alvine evacuations by stimulating peristalsis. Moreover the hydrochloric acid diminishes the intestinal putrefaction, which is singularly exaggerated in this disease, as the author has shown by urinary examinations.

DELIRIUM IN PNEUMONIA.

A recent observation by CASTELAIN (*Archives Médicales belges*) seems worthy of some attention. His observations relate to the delirium which commences just before the crisis, and lasts for several days thereafter. While not ignoring general conditions, alcoholism, debility, the con-

dition of the heart, and circulation, of the brain, and nervous system, of the kidneys, and other organs, he has directed especial attention to the condition in the lungs. During the period of complete hepatization, the lung is impermeable to air; the exudation is abundant but coagulated and compact; the alveoli are filled with fibrine, and young cells, mixed with red corpuscles. Next comes the period of liquefaction, and absorption of the great mass of the liquefied products.

CASTELAIN's observations at this period of the disease, lead him to the following conclusions:

1. The appearance of the delirium coincides with the beginning of the period of liquefaction, and is its first indication.

2. The curve of the delirium is parallel with the curve of liquefaction, and of the abundance of the exudation. The delirium increases during and after defervescence of the fever, in proportion as the râles become more moist and more numerous, and as they extend over a greater area. The delirium diminishes and disappears, little by little, in proportion as the fine râles become less numerous, occupy a less extensive area, and give place to coarser râles and finally to dry râles.

3. The duration of the delirium is in relation with that of the liquefaction of the great mass of the exudate. If the latter is liquefied rapidly and disappears immediately from the alveoli, the delirium is of short duration, but is more violent than when resolution occurs slowly or in different regions in succession. Delirium may even be entirely absent when liquefaction is slow, or the exudation slight.

THE NON-PERMANENCE OF INEBRIETY CURES EXEMPLIFIED.

The sad death of "FELIX OLDBOY," a literateur of New York City, lately, and a warm defender of the KEELEY "bichloride of gold" cure, is reported. He died from alcoholism in the workhouse on Blackwell's Island. He has only recently been represented in the *North American Review* by a long article setting forth the marvellous effects of KEELEY's system in his own person and some other very obstinate cases. These cases were strenuously held to be "permanent" cures, but the ink could scarcely have

been dry on the pages of the *Review* before his last lapse into drunkenness took place. So far as this case is concerned, the KEELEY "cure" was worse than a broken reed to lean upon, since this unfortunate inebriate was induced to ignore and despise the more legitimate measures of relief. The glamour of a false "permanence" misled him, and has probably hastened his final and fatal lapse. This is not said as being peculiar to the KEELEY cure. It is equally pertinent to every other quackish claim to "permanence" in the treatment of the dipsetic propensity. It is not in the resources of chemistry, we hold, or in the pharmacy of the vegetal kingdom, to produce specifics of that nature. The true secret of KEELEY, and every other pretender of his class, who exert any prohibitive influence over the lovers of toxicants, resides in the power of the mind—the superiority of will power—and can properly be included under the head of "mind-cure" masquerading in the garb of drug-treatment. In view of the above, what will be the prognosis in the case of KEELEY? His bubble has burst suddenly in the sight of the whole world, but his decline will not, therefore, or of necessity, be immediate. He may still continue to have a following, more or less noisy and enthusiastic, but his end draws nigh. We have seen just such cases as his, and the history of medicine tells of many others like him, and almost without exception this has been the rule: exposure of fraud eventually brings about its downfall, but it is seldom an immediate or a very rapid decline. Sometimes a fraud shows a considerable vitality, but this is not the rule, when the true facts in the matter have been laid bare.

THE CHINESE FORM OF HIGH DILUTION TREATMENT.

The *North China Medical Journal* is responsible for the following paragraph about an infinitesimally potential treatment employed at the antipodes; it is not improperly called "The Brass Ass Cure." That journal states that a traveler from Pekin says "that he saw a method of cure which may be new to some of our readers. In a temple outside one of the city gates is to be found a brass mule of life size, supposed to have wonderful healing properties. Patients suffering

from every imaginable disease seek this temple to obtain a cure. The method pursued is as follows: Supposing you suffer from sciatica, you go with all speed to this famous temple, and having discovered the particular part of the brass mule corresponding to the painful region of your own body, you first rub the animal a certain number of times and then with the same hand shampoo your own disabled member, and then—well, then the pain goes. The special feature of this method of cure is its delightful simplicity. Is your tooth aching? Just scrub the mule's teeth and afterward your own, and, *voilà!* the cure is complete. Have you an ulcer of the cornea? Pass the tips of your fingers to and fro over the particular eyeball of the mule, and then with well-regulated pressure rub repeatedly the afflicted eye. The mule has unhappily lost his sight during the many years he has been engaged in his benevolent work, the eyeballs, we are told, having been gradually worn away as the result of constant friction, until now you have only the empty orbits to operate upon. The animal is patched in all directions with fresh pieces of brass put on to cover holes produced by the constant friction of eager patients, and a new, perfectly whole mule stands ready at hand awaiting the day when his old colleague, having fallen to pieces in the service, shall give him an opportunity of likewise benefiting posterity."

The reader of the above will recognize that there is in it a reminder of the *similia similibus* principle as well as that of minute dosage.

EDITORIAL NOTES.

THE KÖRÖSI PRIZE.—Dr. Joseph Körösi, of Budapest, has offered the sum of \$300 as a prize for the best essay on the objects of demography and its progress in the chief countries of Europe and America. The competition remains open until January 1, 1894. The award will be made at the opening meeting of the next International Congress of Hygiene and Demography, at Budapest in 1894. The essays may be in either the English, French, German or Italian languages.

THE PISTOJA POWDER REMEDY FOR RHEUMATISM AND GOUT.—A somewhat famous remedy in Italy for rheumatism and gout is the Pistoja powders, so called because sold formerly as a proprietary remedy by the monks of the town of

Pistoja. It is now no longer a secret medicine, thanks to the governmental regulations which at the present time forbid the sale of patent remedies, the composition of which has not been revealed to the proper officials. The formula of the Pistoja powder is said to be:

- R. Colchicum corms, 2 parts.
 Bryonia root, 1 part.
 Betony, 5 parts.
 Gentian, 1 part.
 Chamomile flowers, 1 part.

To be finely pulverized. Mix. Dose at first not to exceed 10 grs.

The presence of colchicum explains why it is that untoward results have been experienced by the non-professional prescribing of this remedy, which was alleged by the monks to be harmless.

THE ANNALS OF HYGIENE for November has taken one of our five line items and given it the very appropriate title of "The Potency of Malnutrition," for which title we extend thanks. Although it was only put at the end of a page to fill space, it was editorial matter.

DOMESTIC CORRESPONDENCE.

LETTER FROM PHILADELPHIA.

The health of the community at the present time is very good. There was a report that diphtheria was prevailing in the western part of the city a few weeks ago, and pending an investigation, one of the public schools was ordered closed by the Board of Directors. It was found that there was an unusual number of cases of catarrhal sore-throat and tonsillitis—possibly an aftermath of the grippe, or due to weather-changes, but only one or two well-authenticated cases of diphtheria could be discovered. The school house was examined by Dr. J. Howard Taylor, physician of the City Board of Health, by whom it was declared to be in good sanitary condition; and it will, therefore, be re-opened at once.

The quality of the water-supply of Philadelphia has for some time been rather severely criticized in the public prints; but there is room for the suspicion that at least some of the advocates for better supply were not entirely disinterested in the matter; their plea was not so much for a better water supply as it was in favor of a certain specific plan, which if adopted would result in the expenditure of a large amount of money on the part of the city to the great pecuniary advantage of themselves or their clients. In spite of the obvious fact that the mortality-rate of Philadelphia is below that of other large cities, and the additional fact that the Schuylkill water has been repeatedly analyzed and pronounced good, even better in quality than the drinking water of New York, Boston and other American cities, the impression seems to have become general that Philadelphia

has a seriously polluted water-supply; whereas the truth is that special attention has been given this matter of late years by the city authorities; and since the construction of the intercepting sewer and the immense subsiding reservoirs in the East Park, and the abolition of some evident sources of contamination, the drinking water of the city has been not only abundant, but of very good quality. The City Councils have just received a report of a sub-committee, appointed to compile a statement from the reports, papers and documents of the Water Department, concerning the water supply of the city, with a digest of their conclusions, acting with the Mayor and the Director of Public Works. The special object of the investigation was to obtain a well-matured decision as to the nature, character and cost of the system to be adopted in future, and incidentally to expose any defects or deficiencies in the present plan of supplying the city with water. The report is full and elaborate; and while it refrains from any definite recommendation, it declares very positively that there exists no necessity for the present generation to take into consideration any other source of supply than the Schuylkill river, as this is shown by all reports; the minimum flow, in case of the heaviest draught in any year, being 225,000,000 gallons in 24 hours, while the maximum over 4,500,000,000 gallons, in the same time. It is advised, however, that action be taken at an early date to prevent useless waste. In regard to the purity of the water, the report claims that it has been clearly demonstrated that if water be taken from Flat-Rock dam, a point above Manayunk, the water will be purer, and the purity could be still more improved by obtaining the city's supply from the Norristown dam, about fifteen miles from the city, the water being brought down by conduits. The statistics of the Water Bureau show that the water from these points is not surpassed in purity by that from any other site along the Schuylkill yet suggested. To make a greater improvement in the quality of the water will bring in the question of filtration, one of vital importance which cannot be ignored, and the argument is made that no permanent relief can be afforded without filtration facilities of the most approved character. This report is now before Council for discussion. A plan has already been adopted for locating a new reservoir for subsiding purposes near the Falls of Schuylkill, and it is probable that in its construction the recommendation of the Committee, with reference to a system of filtration, will be carried out.

The medical schools report progress. At the University of Pennsylvania, the Freshman class is larger than last year. The Faculty, having already a three year graded course, are now agitating for a fourth year to the medical department. Some time ago Professor Pepper announced that such an extension of the course would be made in time, but that an endowment of \$250,000 and a guarantee fund of \$20,000 per annum for five years, would be necessary. Dr. Pepper offered, himself, \$50,000 toward the endowment and \$1,000 per annum toward the guarantee fund. The rest of the money necessary has not yet been obtained, although the subscription is progressing well, so that it is confidently expected that the new course will go into operation in the Fall of 1893.

Students who enter this year are allowed to choose the four year instead of the three year course, and some ten or twelve, thus far, have done so. The new School of Hygiene at the University of Pennsylvania, founded by the liberality of Mr. Henry C. Lea and others, will be opened about February 1st, 1892. The Laboratory building, in which it will be located, is rapidly nearing completion, and is already praised for its beauty and its ingenious construction. It is very clear that the course is to be eminently practical. Every part of the building is a hygienic object-lesson; all the most approved methods of heating, lighting, draining and ventilating are to be tested by actual use. One room has six varieties of steam radiators, arranged so that the efficiency of each, and others if necessary, can be known by accurate measurement. Another room exhibits three systems of ventilation. All sorts of traps and water-closets will be tested in the building. All pipes for drainage, hot and cold water, steam and gas, have everywhere been left bare; each system has its own color, so that it may be readily traced. In many of the laboratory fittings, there are new features, especially adapted to the novel work to be done. The construction has been continually under the supervision of Dr. John S. Billings, who will be the Director of the School, and it appears certain that nothing which could add to the efficiency of the course has been omitted. Besides the course in Practical Hygiene, there will be an elementary course in bacteriology, commencing February 1, 1892; and an advanced course commencing April 2, each lasting eight weeks. These courses are intended to be practical and will include investigations of water, air and soil, the study of pathogenic bacteria, microscopic technique, culture media, protective inoculation and the preparation of vaccines, also details of disinfection, antisepsis, etc. Dr. A. C. Abbott, recently Assistant in Bacteriology and Hygiene in the Johns Hopkins Hospital in Baltimore, has been appointed First Assistant in the Laboratory of Hygiene, and applications for information or admission should be addressed to him at the University of Pennsylvania.

The Medico-Chirurgical Hospital during the summer has been remodeled. Two floors containing rooms for private patients have been added, and a new front of Pennsylvania granite, of appropriate and impressive design, has been built on the street-line. By these improvements, now approaching completion, the capacity of the hospital will be nearly doubled. The wards have been enlarged, private rooms added, and the structure raised from a four-story to a six-story building. The opening takes place with public ceremonies, on November 10. The Medico-Chirurgical College, both in its medical and dental classes, reports good attendance, somewhat in excess of last year at the corresponding period. Prof. Ernest Laplace has a complete bacteriological and pathological course, with excellent facilities for instructing students in pathogenic bacterial culture and microscopic work.

The election of Dr. Jas. C. Wilson to the chair of Practice at the Jefferson has given general satisfaction to the alumni and students, who are also gratified by the arrangement by which Prof. Da Costa continues his medi-

cal clinics, although now only Emeritus Professor of Practice. Prof. Da Costa will also give his usual clinical lectures at the Pennsylvania Hospital this winter on Saturday mornings. In spite of the loss of Prof. Bartholow, and the uncertainty as to who would succeed Prof. Da Costa, the Dean of the College, Prof. Holland, states that the class is about 500, which is quite up to the average number for the last ten years. It may be stated that all our colleges now require evidences of preliminary preparation, and all have a compulsory three years' course. This, taken in connection with the previous statements about the size of the class at each of our schools, should prove to those colleges in other parts of the country, which are fearful of advancing their requirements, that the profession is ready to support them. In connection with the Jefferson, it is an open secret that committee meetings have been held lately, and much debate indulged in concerning ways and means, and details of site and construction for the contemplated new buildings; it being said that the most approved plan will locate the new structure on Broad street, south of Walnut.

So far, this has been by far the most prosperous year in the history of the Philadelphia Polyclinic. All the departments are active, the clinical material which is used in teaching is abundant and varied, and the classes are much larger than they have ever been. The branches to which students are most attracted are, of course, gynecology and general surgery; although the departments of clinical medicine, neurology, diseases of the chest, throat, nose, ear and skin, are all doing active work. During the current month fourteen laparotomies, and numerous other surgical operations, were performed in the hospital before the class. On October 9, Dr. Jackson removed a large ivory exostosis from the orbit. The growth had been noticed for about two years, increasing rather rapidly. The eyeball was pushed forward about 8 mm., and downward 10 mm., but binocular vision was maintained. The exostosis, which weighed $6\frac{1}{2}$ drachms, was removed by drilling holes in the base and breaking the intermediate bone. Its attachment was to the upper, inner wall of the orbit, and the frontal sinuses were opened by its removal. Healing was prompt and uncomplicated, and the sight of the eye was preserved, but there remained a diminishing paresis of the orbital muscles, and some ptosis. Various methods of attack were considered and tried, but the drill was the only instrument that made a satisfactory impression on the extremely hard osseous material of which the tumor was composed.

Dr. Frederick P. Henry, who has been one of the instructors at Jefferson, and was a candidate for the chair of Practice, has been elected to the corresponding chair in the faculty of the Woman's Medical College. Dr. Henry has been for years one of the attending physicians to the Philadelphia Hospital and to the Episcopal Hospital, and Professor of Clinical Medicine in the Polyclinic, and still retains these positions. He is an able pathologist and lecturer, and is a decided acquisition to the Woman's College.

A special meeting of the County Medical Society was

held just after the close of the recent Triennial Congress of Physicians and Surgeons at Washington, in honor of some of the foreign visitors who stopped over in Philadelphia for a brief rest, and to recover from *mal de Washington*, or Potomac quickstep, which during the late International Congress almost assumed the proportions of an epidemic, especially among the English members. The subject discussed at the special meeting of the County Medical was "Appendicitis." Papers were read by Dr. W. W. Keen, Dr. Joseph Price, and Dr. Thos. S. K. Morton, and a case was presented by Dr. Frank Woodbury, upon which an operation for excision of the appendix had been done by Dr. Thos. G. Morton, five years ago. The discussion was opened by Dr. Wm. Pepper, and was continued by De Forest Willard, Hare, Baldy and others. Mr. Thomas Bryant, of London, one of the guests, while favoring operation, urged the advisability of delay in operating in the majority of cases. Cases should be divided into those which are acute from the beginning, and which require prompt relief, and others, not acute, having a slow and steady progress. The latter begin with a localized pain in the right iliac fossa, accompanied with tenderness and soreness, and, less swelling; and according to Mr. Bryant, these can be dealt with satisfactorily without the surgeon's knife. The line of treatment approved by Mr. Bryant would not be that recommended by Dr. Morton, of calomel and podophyllin in frequently repeated doses, but he would prefer to rely upon rest and diet, belladonna externally and opium internally, believing and knowing that by such means the bulk of the cases are permanently cured. In exceptional cases, where these good results do not follow, and graver symptoms, increase of swelling and symptoms of peritonitis, appear, the surgeon's aid becomes of immense value, and certainly where these symptoms do appear, and there is a steady progression toward the bad, it is unquestionably time for the surgeon to take a hand. In all acute cases he does not question the right of the surgeon to interfere. As regards the propriety of operation between the attacks, his judgment would oppose it. He had seen many cases, in which even after a second attack, things have settled down and no further trouble developed. He advised that each case should be considered as a law unto itself, and the surgical interference is obligatory only when we find small chances of nature terminating the case favorably when guided by medical skill. With regard to the operation, he preferred the lateral incision, in some instances as far back as the line of the anterior superior spinous process and tending backward toward the loin. He deprecated too much disturbance of the parts in searching for the appendix, believing that better results can be obtained by irrigation and treating the wound by the open method. In conclusion, he pointed out the fact that all cases of typhilitic trouble and abscess are not due to the appendix, as some may be caused by the ulceration of the cæcum or foreign body, such as a bone or orange seed, cases of which he cited. During the stay of the visitors they were well entertained. Dr. John B. Roberts, President of the County Medical Society, gave them a reception, at which were

present, Prof. Chiene, of Edinburgh, Dr. Wm. Gairdner, of Glasgow, and Sir William Mac Cormac, Mr. Thomas Bryant, Mr. Arthur Durham, Mr. Reginald Harrison, of London, to meet whom Dr. Roberts invited the members of the Society and physicians from other cities.

While speaking of societies, it is well to note that the gynecic imbroglio at the College of Physicians, which caused so much stir last spring and went so far as to cause the Board of Censors of the college to tender their resignations, has now been resolved and matters are now flowing in their accustomed peaceful channel. This was accomplished by the action of the college at its last meeting, when a resolution of censure was passed upon Dr. Joseph Price for expressing his private opinion of Dr. Penrose and other Fellows of the college somewhat too frankly, and the verdict of the censors that Dr. Price be requested to resign from the college was concurred in. It is understood that the censors have withdrawn their resignations, and Dr. Price shows no undue haste in offering his resignation, and probably will not do so at all. While the results of the commotion do not seem commensurate with the expenditure of force, or in other words, the amount of feeling that was stirred up, it is quite certain that the lesson will not be lost, and that the experience will be a salutary one in medical ethics, the good effects of which will be manifested hereafter.

The Pennsylvania Hospital will soon be enlarged; the managers having decided to erect another wing, which will add about 150 beds to its capacity. The new building will be upon the Spruce street front. It will be devoted to medical purposes and will have modern appliances for heating, ventilation, bathing, etc. The present buildings will probably be entirely surgical. The clinical hall will remain in its position between the present and the proposed buildings.

At his clinic, at the Pennsylvania Hospital, October 24, Dr. Thos. G. Morton exhibited the calvaria of a case of suicidal gun-shot wound of the brain. The young man was nineteen years of age, and was found in his room at a hotel with a bullet wound in his forehead, a little to the left of the median line. He was brought to the hospital at once, unconscious, and with right hemiplegia; he would occasionally lift his left hand to his head and grasp his hair as if in pain. Dr. Morton was out of the city at the time, and did not see him for two days. He found that a long probe could be passed directly through the left hemisphere until it met the parietal bone. Dr. Morton then trephined and found a softened collection as if the posterior convolutions had been churned up by the ball after it was checked by coming in contact with the inner table of the skull at this place. By inserting the tip of his little finger, he was enabled to detect the ball a short distance below the opening made by the trephine, and to subsequently remove it. The case was treated antiseptically, and a rubber drainage tube was passed directly through the brain along the track made by the bullet. The patient improved after the operation; he did not speak, but his eyes followed the movements of those about the room as if he were conscious. Three days later he died from exhaustion. Dr. Morton advocates the treatment of wounds of the

brain in the same manner as other wounds, by asepsis and drainage, and the use of the trephine if necessary to fulfill these objects. At the same clinic, Dr. Morton exhibited a calculus, cylindrical and tapering, resembling a thick date stone, which he had removed from the appendix vermiformis of a man, in the interval between attacks of appendicitis. The stone appeared to be phosphatic, and in drying became friable and easily separable into layers. The patient was also shown, having made a very prompt recovery. The operation was undertaken on account of the persistent tenderness remaining in the appendix region, and a hard object could be distinctly felt by deep palpation in this location.

At Jefferson Hospital, Dr. J. Solis-Cohen recently operated by Rouge's method for the removal of an epithelioma of the right middle turbinate body. The patient was a woman about sixty years of age. In this operation, the incision is made in the mucous membrane of the upper lip and the soft parts are separated successively from the bone and slid upwards so as to make a "death's head." The advantages are more freedom of access to the nasal chambers and absence of external cicatrix. The morbid growth, which was quite soft, was thoroughly scraped away and its base seared with the galvanocautery.

A daily medical journal has commenced publication in Philadelphia, published by Dr. Jos. F. Edwards, the enterprising editor of the *Annals of Hygiene*. Subscription price, ten dollars per annum. The daily medical journal has frequently been discussed by medical editors and recognized as a long-felt want; but Dr. Edwards comes along and like a modern medical Columbus takes up the pullet's egg and smashing in the end, makes it stand alone and shows an admiring world how it may be done.

Section of Physiology and Dietetics.

To the Editor of the *Journal of the American Medical Association*:

Dear Sir:—The Section of Physiology and Dietetics should be a mirror of the present knowledge of the American Medical Association; those members who have any new points in physiology and dietetics will please send the titles of what they propose as their contributions to the common stock of knowledge. The officers of the Section could fill the whole time with papers and demonstrations, but this would infringe on others' rights and make it too much of an individual affair. There is no prescription of subjects, as this would be a restriction on the broad and open treatment that is due to workers in this department. Still practical points as to food will be very acceptable in the hope that better days as to diet may sooner dawn.

By order of Chairman, C. H. Kleinschmidt, M.D.

Ephraim Cutter, M.D., Secretary.

The Ariston, 1730 Broadway, New York, Nov. 5, 1891.

Codeine and Narcine.

Ed. The Journal:—I have read with much interest Dr. J. B. Mattison's paper on Codeine and Narcine vice Morphia. I write this note to indorse with emphasis every word Dr. Mattison says in favor of codeine over morphia. I have used codeine daily for more than fifteen years to the entire exclusion of morphia, and never had any one to form the codeine habit, and never increase the dose.

I am sir, very truly,

CHAS. MANN.

BOOK REVIEWS.

DIAGNOSIS AND TREATMENT OF HÆMORRHOIDS AND OTHER NON-MALIGNANT RECTAL DISEASES. By W. P. AGNEW, M.D. Cloth, small 8vo, pp. 146. San Francisco: R. R. Patterson. 1891.

This book is principally devoted to recommendation of the treatment of hæmorrhoids by carbolic acid. The author's directions for making rectal examinations are excellent, and the author has given some valuable suggestions for treatment of these troublesome affections.

While the author's experience with carbolic acid is at variance with that of Andrews and others who have made a study of it, we cannot close our eyes to the fact that the "irregulars" are making the most of its use, and that there must be a much larger proportion of cures from it than is commonly supposed by the profession generally. It is really worth while to ask whether, in throwing away carbolic acid, we are not rather yielding to our disinclination to adopt anything from outside the professional pale.

We infer from frequent references to persons known to be "homœopathic," that our author belongs to that ilk, but nothing in the prescriptions, or the pathology, or the treatment, shows any heretical teaching of that sort, and we commend the book.

ESSENTIALS OF BACTERIOLOGY. By M. V. BELL, M.D.

This is one of Saunder's Quiz Compends, and one of the most useful of them. A small and comprehensive manual on bacteriological methods is a *sine qui non* to the student. This fulfills the demand.

OBSTETRICAL NURSING. By ANNA M. FULLERTON, M.D. P. Blakiston & Son, Philadelphia.

This little volume should have an extended sphere of usefulness. Detailed instruction on this subject is very essential to the prospective nurse who is attempting to grasp general principles simultaneously with practical matters gleaned from every-day experience.

MISCELLANY.

INTER-COUNTY MEDICAL SOCIETY.—The second regular meeting for the current year of the Inter-County Medical Society will be held at West Superior, Wis., in the parlors of the Broadway Hotel, Tuesday and Wednesday, November 10 and 11, 1891.

COMMITTEES.

Arrangements.—L. B. Shehan, Chairman; All Members at West Superior.

Practical Medicine.—J. B. Trowbridge, Chairman; S. L. Pickett, H. Hannum,

Surgery.—E. S. Hayes, Chairman; M. S. Hosmer, W. T. Rinehart.

Obs. and Dis. of Women and Children.—H. E. McIntyre, Chairman; H. V. Scallon, W. H. Ellis.

Special Gynecology.—J. V. R. Lyman, Chairman; A. E. Bonneville, C. V. Beebe.

New Remedies and Therapeutics.—D. H. Decker, Chairman; W. T. Leonard, W. C. Pease.

Elementary Branches.—F. W. Epley, Chairman; J. A. Rene, H. B. Weiper.

Finance and Publication.—J. B. Trowbridge, Chairman; C. A. Hayes, D. H. Decker.

PROGRAMME.

The following is a partial list of subjects to be presented and discussed:

Tumors in Unusual Places, by Dr. C. A. Wheaton, St. Paul.

Familiar Talk on Gynecology, by A. J. Stone, St. Paul.

Enterocolitis, by C. S. Beck, Jr., West Superior.

Fractures of the Skull, by E. S. Bacon, West Superior.

Appendicitis, with Report of Two Unique Cases, by W. E. Ground, West Superior.

Marginal Blepharitis, by D. D. Conkey, West Superior.

Crime an Evidence of Disease, by F. G. Sherwood, Superior.

Laparotomy: Report of Twenty-six Cases, by J. V. R. Lyman, Eau Claire.

Scarlet Fever, by A. F. Heising, Menomonie.

Errors of Refraction and their Relation to Headache and Other Reflex Neuroses, by F. R. Reynolds, Menomonie.

Appendicitis with Abscess, by S. L. Pickett, Wilson.

Acute Enterocolitis, by H. E. McIntyre, Hudson.

Fatal Chorea, by J. B. Trowbridge, Hayward.

Practical Remarks on Neurasthenia, by I. D. Wiltrout, Hudson.

Laparotomy and the early removal of Ovarian Tumors, based on result of Forty Cases, also Subsequent Symptoms, and the Cases indicating Drainage, by A. E. Bonneville, Ashland.

Urethritis, by J. A. Rene, West Superior.

WHITE OF EGG IN THE TREATMENT OF SORE NIPPLES.—F. Van Allen, M.D., writes to the *New York Medical Journal* of three cases in which he found white of egg, painted on sore nipples several times a day, entirely healed them in a few hours.

The albumen may best be applied just after nursing, while the nipple is still moist from the baby's mouth. As somewhat of a thick film is formed, it is well for the nipple to be moistened with a soft cloth dipped in water just before the baby is again put to the breast. The efficiency of the albumen is heightened by allowing it to dry on thoroughly before drawing the clothes again over the breast.

AUSTIN DISTRICT MEDICAL SOCIETY.—The seventeenth quarterly meeting of the Austin District Medical Society and joint session with the Central Texas Medical Association, will be held at Austin, Texas, Thursday, December 17, 1891.

Programme.—Morning session, 10 o'clock.

1. Address of Welcome.

2. Reading of Minutes.

3. Applications for Membership.

4. "Enteritis Simulating Bowel Obstruction," by Dr. Daniel Parker, of Calvert; discussion opened by Dr. J. M. Frazier, of Waco, and Dr. W. A. Howard, of Waco, all of the C. T. M. A.

5. "Perityphilitis," Dr. W. R. Blalock, of McGregor, discussion opened by Dr. G. B. Foscue, of Waco, and Dr. W. E. Brown, of Gatesville, all of the C. T. M. A.

Afternoon Session, 3 o'clock.

6. "Is Syphilis Transmitted Directly from the Father to the Child?" Affirmative: Dr. C. O. Weller, of Austin; Negative: Dr. W. T. Richmond, of Manor, both of A. D. M. S.

7. "The Management of Abortions," by Dr. J. W. Carhart, of Lampasas; discussion opened by Dr. T. D. Wooten, of Austin, and Dr. G. W. Christian, of Burnet, all of the A. D. M. S.

8. Voluntary Papers.

9. Verbal Reports of Cases.

10. Unfinished Business.

11. New Business.

12. Election of Officers.

13. Retiring President's Address.

14. Banquet at Night.

The Society will meet in Medical Hall, 513 Cong. Ave., and be called to order promptly at 10 A.M.

J. W. McLAUGHLIN, President.

T. J. BENNETT, Secretary.

TO SAVE THE BABIES.—There are over one hundred babies born out of wedlock every month in the Public and Private Hospitals of Chicago. Nearly all of these babies are offered for adoption by their mothers when they are two or three weeks old, but being unable to give them away they place them in the baby farms or boarding houses to die of a slow death, or they dispose of them by other questionable methods.

Their mothers are not hardened criminals or women of the town. They are deceived young women from our factories and workshops who have been led astray. Many of them are from country towns and have been sent to Chicago for hospital service.

The babies are generally two or three weeks old when offered for adoption. Most of them are healthy, strong babies, entirely free from inherited disease, black eyed babies, brown-eyed babies, blue-eyed babies, blondes and brunettes, of every nationality, and they are finer specimens physically and mentally than the average run of children born in wedlock.

The Children's Aid Society of Chicago has undertaken the rescue of these babies from an untimely death, and they ask the coöperation and assistance of all practicing physicians. In case of the death of an infant anywhere in the country we ask that the attending physician will recommend to the bereaved mother that she adopt one of these babies and nurse it and raise it as her own. If the doctor will send immediately a description of the lost baby, we will duplicate it from the large number offered for adoption and send it by the next train to its new mother. The selection will be carefully made by a competent physician to secure a perfectly sound child.

The only expense to the receiver of the child will be the railroad fare of the nurse who brings the child.

Address the Children's Aid Society, P. F. Chase, Supt., Room 44, No. 204 Dearborn St., Chicago.

NEW YORK STATE MEDICAL SOCIETY.—The next meeting of the Medical Society of the State of New York will be held at Albany, February 2, 3 and 4, 1892. Dr. Seneca D. Powell, No. 12 West 40th street, New York; Dr. James D. Spencer, of Watertown, and Dr. Franklin Townsend, No. 2 Park place, Albany, have been appointed the business committee. Any communication regarding papers or any matter pertaining to the business of the Society which should properly come before the business committee, should be addressed to Dr. Seneca D. Powell, 12 West 40th street, New York City. A. Walter Suiter, president; F. C. Curtis, secretary.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending November 7, 1891.

Surgeon Manly H. Simons, ordered to U. S. S. "Mohican." Medical Inspector Frank DuBois, ordered to U. S. S. "Philadelphia." Medical Inspector T. Woolverton, detached from U. S. S. "Philadelphia," and ordered before Retiring Board. Asst. Surgeon N. J. Blackwood, detached from U. S. S. "Newark," and ordered to Navy Yard, League Island, Pa. Asst. Surgeon C. DeW. Brownell, detached from Navy Yard, League Island, and ordered to U. S. S. "Newark." P. A. Surgeon Philip Leach, detached from the Naval Academy, and ordered to U. S. S. "Monocacy." Asst. Surgeon John E. Page, detached from the U. S. R. S. "Independence," and to the U. S. S. "Iroquois." Asst. Surgeon James G. Field, detached from Bureau of Medicine and Surgery, and placed on waiting orders.

LITIGATION DISEASE A FORM OF NEUROSIS.

*Read in the Section on Medical Jurisprudence and Neurology, at the
Forty-second Annual Meeting of the American Medical Association,
held at Washington, D. C., May, 1891.*

BY HERBERT JUDD, M.D.,
OF GALESBURG, ILL.

During the fall of 1881, E. S., aged 60 years, in form tall and slim, temperate habits, previous health always good, a noble specimen of average humanity, occupation farmer and dealer in stock, an expert in this line of business, was on his way to Chicago from W., Iowa. While at a feeding station he was standing in the rear door of the way car looking out, the train was backed to way car with such force as to loosen the upper bunk next the door at his right side; as the bunk fell into its place it struck S. on the right shoulder and arm, and also caught the right hand, crushing one of the fingers; the finger was at this time dressed with a rag at hand by the other stockmen. S. completed his trip to Chicago, nearly two hundred miles, made a satisfactory disposal of his cattle and returned home. The accident and injury being noised about, a lawyer called himself into the case, a doctor was employed, and after a short time suit was brought against the railroad company.

On the morning of March 14, 1882, I was called from breakfast at my home in Galesburg, to the door, to find E. S., who, in the way of introduction, handed me the card of a prominent railroad attorney in Chicago. Inviting S. to breakfast, the above history of his case was learned. The man's appearance was favorable. He seemed to be unable to use his right arm and hand, the arm being carefully carried in a sling, with the hand between a button space in his outer coat. He fed himself with his left hand. Having been injured some six months previous, he had acquired this habit, and had become an adept at feeding himself with his left hand. There was not a line of pain about this man, and his every appearance would indicate to a close observer a strictly honest, conscientious person. He appreciated every courtesy shown him, and after

reaching my office, myself and assistant, having ascertained that the finger had never been dressed or redressed since the time of the accident, some six months previous, we suggested to him that it was time to remove the filthy crust about the finger. He acquiesced in this. After getting the finger bare, it was found to have been thoroughly and properly healed for months; thereupon we suggested, as nicely as possible, the shoulder and arm had also recovered. To this suggestion a prompt denial was made, although accompanied with a candid declaration that aside from extreme care used when a change of clothing was necessitated, no attempt was made to use the shoulder or arm since it was first examined and put in a sling some six months previous. S. was afraid of being hurt; he said he was willing for us to examine him; that he wanted to do what was right and fair; that he knew he was injured, permanently injured, but other persons, whom he had no reason to suspect or distrust, had plainly told him there was nothing the matter with him; that he had been sent to me for examination, and was willing to submit to what was right, but he did not propose to be hurt. "I want to be fair and honest with everybody as far as I know," was what he said. We proposed to administer chloroform to him in order to make an examination and to do the necessary manipulation without causing him pain. He sternly refused, and as a reason stated that he had been instructed by his lawyer and by his doctor not to take chloroform for an examination. We spent one hour patiently in getting this man stripped. In the meantime a Drescher faradic battery had been placed on a table conveniently near, and after much persistent childish persuasion we did get him to clasp in each hand an electrode, with the primary current mildly established, then by suddenly turning the switch the secondary current was established, and the withered shoulder and arm responded naturally in a lively manner, and without pain. He was sitting before a large mirror, and as he witnessed himself in his curious gymnastics, he became first frightened, then angered. Matters being brought to a close, time was given him to realize his condition and think about his situation, which resulted in this state-

ment from him: That until then no one could have made him believe there was nothing the matter with himself. He could easily and naturally move his shoulder, arm and hand, and aside from the wasted condition of the muscles, and the palsied appearance, everything was right and had been for months and months. He cried with joy, then he scolded himself in disgust. He said he was willing to do anything to keep from further disgrace. The railroad company had months previously made this man a liberal offer in money for his injury, but suit had been brought in his behalf against the company for a large sum based upon permanent injury. He quietly took the money that had been offered him, and a speculation lawyer was out of a job.

We believed from the first that this man was honest. We afterwards ascertained that he bore a good name, but that he was ignorant outside of his own business, and that he was easily influenced. He was told by *interested* persons that he was injured, permanently injured, and his cupidity overpowered his judgment. No practical attempt had been made to convince him that he was recovered, and that he was not still suffering from his injury, before I saw him. The demonstration that there was no paralysis in the shoulder or arm was so simple and clear that he was overpowered with joyful emotion, simple and natural in its character. The experience and knowledge gained in this case have caused me to follow up and watch other cases of a similar character, cases in which suits have been brought and judgments of large amounts have been paid, and which were, after settlement, followed by a speedy convalescence and total recovery,—cases which previous to settlement had been bed-ridden for a term of years, and during the trial were pronounced by high medical and legal authority in court as being permanently injured, hopelessly so—two cases in which death was predicated within the space of three or four years in the presence of the court, and within the hearing of the *condemned* plaintiff.

I have cited the case of E. S., for the reason that it is typical of this class of cases. It is clean cut and can be identified. The injury was slight and simple, but nevertheless was made the basis of an important suit at law to recover heavy damages for an alleged permanent injury. It is the small and simple things, neglected in this world, that cause most of our trouble. I believe that such persons can be said to be suffering from "*litigation disease*;" that this condition can be truthfully stated as a form of neurosis in which fright, or shock, temporary disturbance from business, and many other trivial things, naturally figures, which under other circumstances would be unaccountable, and that in all of these cases the proper course to pursue must be kind attention properly administered, and in

all cases where the question of liability for damages is conceded, a prompt and liberal payment of money on the part of the corporation or railroad company should be made—a functional nervous disease will then be rapidly and permanently cured; that it is safe and humane to look upon these cases as a form of functional nervous disease, meaning of course the class of cases as illustrated by E. S. I never had the heart to style S. as a malingerer. I do not believe he knew any better. He was told by *interested* persons that he was injured, permanently injured, and that the railroad company was liable, and could be made to pay a large sum of money—all of which he believed; and the part he most believed and knew to be true was that he was injured, permanently injured; and here is where I think I am warranted in bringing this paper before you. It is to call your attention to the peculiar condition of a person who has been in an accident and who was at that time injured, and wherein is conceded the payment of money to him for the damage done him. We all know that a functional nervous disease can be made organic, lasting, permanent, and it is certainly hard, impossible sometimes to demonstrate that such a person has not received a permanent injury; that he is not suffering from an organic disease caused by his injury, incurable in its character, and possibly progressive as regards bad results or death. Particularly is this the case in *neglected* cases that are solicited by *interested* persons, and placed in litigation; cases in which it is certainly easier and more natural to exaggerate than it is to simplify or improve. I never knew but one man to get better, to improve on a line of recovery while his case was being litigated, and I expect to have to look a long time before I find another. It is out of the line of ordinary humanity. It is a fact that such cases are knowingly or unknowingly terribly abused; that justice relative to them is travestied. These cases are put in court, and verdicts for enormous sums are obtained and paid. Permanent injury is alleged and proven to the satisfaction of the court and jury; death is even predicated openly in court, and with no respect paid to ordinary rules of medical practice, and after all this has been so skillfully done such cases have been known to recover, rapidly recover. It is a fact that this is the rule, and not the exception in this class of cases.

Railroad companies, corporations and cities in this country are paying millions of dollars to such persons. The Government is doing the same. The advantage and the gain is with all such. They have nothing to lose. If the machinery to run such a case in one city is not complete, the patient is packed off to another city. Some noted specialist in nervous diseases is reached through his cupidity. No dishonesty

can be attached to him. The electric battery is called into use. *The reaction of degeneration* is found. Organic disease is supposed, and *claimed to be proven*; actual cautery even, is applied along and over the spine, and this, too, in a case that bears every aspect that the patient may succumb under this terrible treatment, and the wonder is that he did not. I am no expert lawyer. I am no expert doctor, not even a medical professor, but fortunately or unfortunately it has been my lot to witness just such cases and to see just such procedures as herein detailed, and I am here to cry HALT. I never have seen nor do I expect to see a case of pronounced legitimate injury in court and under trial for money to be paid, wherein the question of liability has been concerned. This is a hard statement, but the facts are prolific, extremely abundant, existing all through this country, that bear me out in the statement. I find my sympathy with this non-malingering class of cases. They are certainly *injured* persons in more ways than one. They are practically suffering from functional nervous disease; I have styled it "litigation disease," a form of neurosis, same as we call certain nervous conditions hysteria, and other functional nervous conditions neurasthenia. These persons are so conditioned as to be beyond self-control. They have, in a *hasty* and *unpremeditated* manner, signed away their liberty, and this in a free country. They are being fitted for a legal race, in which they are bound to win, regardless of all professional honor and integrity. Whether as yet this practice can strictly be called fraudulent, remains in some cases to be seen, to be found out. The results certainly bear out the conviction that somebody was terribly mistaken.

In discussion, Dr. Clevenger said :

Mr. Chairman and Gentlemen : The scientific aspects of Erichson's disease are obscured, and all that concerns the matter of spinal concussion is wrangled over for the very simple reason that there is money involved. I may say it concerns contention over millions of dollars. Were typhoid fever, or any similar complaint, dragged into court and made the basis of a money issue, there would instantly arise a host of interested parties claiming that there was no such disease. Where the carrion is, the buzzards will gather, and lawyers seek out witnesses who best serve their particular side. They do not want the judicial-minded physician (unless they have a very strong case), and both for plaintiff and defendant we too often see (*not always, but too often*) the buzzard doctor swearing sturdily to anything, almost, that his attorney requires. By a process of elimination, the unpurchaseable physician (and there is plenty of him) is less often seen in court, and the buzzardy swarms are contemptu-

ously regarded by juries, judges and lawyers as constituting "experts."

But the expert standard is gradually being raised, and it suffices no longer that the witness may ventilate himself of an opinion; he must now give reasons for his belief.

The bombastic surgical bluffer who pooh poohs at the lost leg, and congratulates the victim upon his freedom from corns and bunions, has had his day, as well as the calamity doctor, who rears mountains out of molehills.

There is a golden mean in this matter that can be arrived at by a little study. Dr. Rohr recently called me to the case of Fred Schultz, who two years previously had fallen from a stool backward upon a pile of bricks, and suffered all the characteristics of Erichson's disease, finally dying therefrom, notwithstanding that there was no damage claim, and his ignorant neighbors had declared that he was only lazy, and wanted to escape work by pretending to be sick. On the other hand, at Frankfort, Indiana, the case of George E. Miller against the Monon road ended in establishing the fact that he had filed a pension claim just one month before the wreck, and his pension application contained the sworn statement of a spinal injury sustained in 1864, disabling him from earning a living, while his declaration against the railroad alleged the same thing as resulting from the railway accident, and that previous thereto he had been strong and healthy. As both these statements were judicial affidavits, there would be considerable difficulty in determining which should be believed.

Dr. Watson's experiments, as stated by himself in his recent publication, do not justify the deductions he makes from them; in fact, there is little connection between his facts and inferences, and, further, the experiments themselves bear very little upon the subject.

In last year's Surgical Section, Dr. Watson took occasion to speak of the alienist as cultivating a "pseudo science." So ill-advised an assertion convicts him of not possessing the "mental breadth" he has just mentioned as necessary in the investigation of spinal concussion.

Dr. Spitzka recently called my attention to an article by Hans Ichmans in *Virchow's Archiv*, p. 326, vol. 122, strongly sustaining my claim of tangible results in Erichson's disease, and time does not permit me to more than allude to Oppenheim's statement (*Neurolog. Centralblatt*, Aug. 15, 1889): "In the majority of cases the symptoms unite to form a type of disease which cannot, in the present state of our knowledge, be mistaken, from its significance, its clearness, its objective character, and the sharpness with which it is defined. In the policlinic where I examine such cases before a large audience of students and physicians, in almost three-quarters of the cases I develop the diagnosis in a convincing

manner on the first examination, so that I often hear the question, 'How is it possible that such diseases should be regarded as simulated?'"

Dr. King said that he would like to know what constituted spinal concussion.

Dr. Hughes requested Dr. King to tell us what was the lesion in cerebral concussion, and we might be able to answer his question as to spinal concussion.

Dr. Lydston asked Dr. King if he believed in surgical shock.

Dr. King said that he did.

Dr. Lydston then asked for its pathology.

Dr. King: Hæmorrhage.

Dr. Clevenger: What organs are affected?

Dr. King: The whole man.

Dr. Clevenger: So is the entire man affected in spinal concussion.

Dr. G. Frank Lydston said:

Too much stress has been laid upon the nomenclature of spinal, and especially railroad spinal injuries. As the term spinal concussion is generally applied it is not remarkable that there should exist so many conflicting opinions. Concussion of the spine as an entity does not exist, neither in my opinion does concussion of the brain. But that certain varying symptoms dependent on widely different pathological conditions may result from a jarring of the cerebro-spinal axis, must, I think, be admitted.

I have this to say of the theory of molecular vibration as a cause of the symptoms following spinal injuries. The most rational theory of nervous conduction yet advanced is that of molecular motion now if we may except this view we must believe that disturbances of the normal molecular arrangement of the nervous structures will almost necessarily produce aberration of nervous function and, if these disturbances be severe, it is rational to expect permanent morbid effects in a certain number of cases.

The argument has been advanced here to-day, that "spinal concussion" has not occurred unless there be anatomical changes in the cord. This is begging the question. Must we hit our patients in the head with an ax so that we may examine the cord for anatomical lesions? Is it necessary to see the ileum in typhoid in order to believe in the existence of such a fever? Is tetanus none the less real because of its obscure and scant morbid anatomy? Must we throw every functional disease out of court because there is no morbid anatomy? No, and yet that is what the railway surgeon proposes to do with spinal concussion. Accept the view that concussion is a physical influence upon the spinal cord, which may produce a varying degree of morbid phenomena according to the severity of the jarring, and the subject will be divested of much of its confusion. It is to be remembered that the tissue protoplasm of the cerebro spinal axis may be acted upon by

jars in very much the same manner as the amœba by an electrical discharge. It is probable that the cause of death by lightning or electric current is a severe concussion of the nerve tissue, inhibiting the energy of the protoplasm of the nerve cells.

Dr. Manley speaks of the manner in which the spinal fluid acts as a water bed in the protection of the spine. I fancy this water bed does not stand the criminal who is hung in good stead, it certainly does not completely defend the spine from jars. Indeed I fancy there is more of compensation than design in its presence in the spinal canal—its presence is due to the necessity for filling the vacuum incidental to the loose and mobile texture of the envelopments of the cord. It is possible that it favors rather than otherwise the transmission of jars to the cord.

There is one question that I should like to ask of those who do not believe in the theory of spinal concussion. Can you tell me the precise condition in surgical shock? Can you determine in fatal cases that the patient died of shock, by the morbid anatomy present? I fancy you cannot, yet fatal cases do occur, and short of a fatal result we meet with not a few cases of chronic invalidism. The assertion that a person who has suffered from a railroad injury is "never the same man again" is not without foundation. We cannot throw all the neuroses in which there are no anatomical lesions, out of court, and yet, that is what we are asked to do in the case of railway spine, or Erichson's disease.

Laying all theory aside, the practitioner is confronted with many cases in which the settlement of damages does not cure the case, and many in which they even get worse after settlement. There are many frauds perpetrated against railroads it is true, but in the aggregate I think the roads get the best of the bargain.

Both sides must be fair and charitable. A few isolated instances of surgeons who sell their souls to railroad corporations do not prove all railroad surgeons to be knaves; a few mistakes should not stamp all of them as ignoramuses. On the other hand, an occasional fraud does not disprove the honesty of a large class of railway litigants. Let us lay personalities and recriminations aside and seek for the truth in these cases.

In my own experience I have seen a case of lateral curvature which I believe to have been due to a concussion of the spine from a fall upon the buttocks. This developed within a few weeks after the injury and was attended by spinal tenderness, neuralgia, etc. In another case paralysis of the serratus magnus seemed unquestionably to be due to spinal concussion. Dr. Moyer is now treating one of my cases in which most profound nervous symptoms have developed—without paralysis—chiefly since her case was satisfactorily settled by the railroad.

PARETIC DEMENTIA AND LIFE INSURANCE.

Read in the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY JAS. G. KIERNAN, M.D.,
OF CHICAGO.

FELLOW OF THE CHICAGO ACADEMY OF MEDICINE.

The increase of paretic dementia among civilized nations has created many important legal problems for solution. The present question has puzzled the solicitors of more than one insurance company. In a case which came under my own observation, a paretic dement insured his life. A month later he was adjudged insane and sent to the Cook County insane hospital, of which I was then Superintendent. Eight months later he died in an apoplectiform attack.

Dr. S. V. Clevenger has had under care a commercial traveler addicted to sexual excess and luetic, who, precedent to May 6, 1889, had spinal symptoms of paretic dementia, following which came a condition of emotional exaltation. His life was insured precedent to the spinal symptoms for \$5,000. In a period of emotional exaltation he desired to increase this to \$20,000, which was done in January, 1890. June 4, 1890, he died in an apoplectiform attack. The solicitors of the company wrote to Dr. Clevenger to know if the patient *knew* he was suffering from insanity when he consulted the doctor. After such a bright attempt to manufacture evidence of fraud, it is not surprising that the company had to pay the full amount.

Legrand du Saulle¹ reports the following case: Dr. Blank, a physician well known in science, had had for more than nine years an insurance of \$20,000 on his life. He suddenly gave unequivocal evidence of mental impairment, went and came rapidly, wrote and spoke a great deal. He had an exaggerated opinion of his labors, vaunted his success in practice, and boasted of his professional ability. In one of his walks he accidentally met the President of the company in which his life was insured. After a long conversation, Dr. Blank said that his life was insured for an insignificant sum, and that he had resolved to increase the amount to \$100,000. He was referred to the proper authorities, who consented. The policy was prepared, and all that was needed to complete the assurance was a receipt for the same. The agent, who was ready to deliver the policy on the signature of the receipt, suddenly noticed, just as the doctor was about to sign this, that the latter talked rather freely and loudly. Suspecting intoxication, he put off delivery of the policy until Dr. Blank should become sober, claiming to have forgotten some important formality. The following day the physician was sent to an hospital for the insane, where he died in six

months from paretic dementia. The company paid the \$20,000 to his widow, and esteemed itself happy that it did not have to pay the \$100,000 for which the husband had desired, in a fit of pathological temerity, to assure his life.

The intellectual powers of a paretic dement are such as make him an easy prey to the blandishments of any "sharp" insurance agent who would believe him, from his apparently excellent health, to be a good risk. Once started in the life insurance direction, the paretic dement might keep on, like Legrand du Saulle's patient, increasing the insurance on the life of the valuable citizen he believes himself to be, since paretics have a tendency to adopt and extend ideas derived from others, as shown by the case of the paretic dement cited by Spitzka, who, saved by his wife from a paretic suicide, proposed to erect a monument to her for saving the life of so valuable a citizen. It is curious how often this psychosis escapes observation by the non-alienist physician and laymen, when compared with the ease with which it is diagnosed by even asylum attendants familiar with it. In two cases which occurred in New York State, two cashiers of banks who had been paretic dements for at least two years, nearly brought the bank to a condition of insolvency by simple lack of attention to business, but their mental condition had not been at all suspected by their business associates. A Chicago saloon keeper with a paretic delusion of having inherited \$2,000,000, was interviewed by the reporters of every paper in the city, by none of whom was his mental condition suspected until his friends took measures to have him placed under treatment in the county hospital for the insane. There is, therefore, nothing antagonistic to the existence of paretic dementia in the fact that a man insures his life for a large amount, and his mental condition escapes observation from the business men of the company. It may, however, be urged that the medical officers of the companies would detect the psychosis. He who knows how these medical officers are chosen, either from relatives or connections of the officials of the companies, or by agents who tell the physician that "he must not be too strict," or for political reasons to influence State Legislatures, from medical politicians (who indulge in "graveyard" insurance dodges in which they get caught sometimes, but not as a rule), will scoff at the idea that men like these, who neither know nor care to learn anything of psychiatry, could be of value in the detection of insanity.

The same point is still more strongly illustrated by another case cited by Legrand du Saulle: Two brothers presented themselves at the office of a French alienist. The elder brother entered the office first, and asked the alienist to examine with care the patient brought him. "There

¹ *Caz. des Hôpitaux*, 1884.

seems to be nothing the matter with my brother," said he, "but he is no longer the same." The physician, after a long examination, said: "Your brother is in the initial stages of paretic dementia." Explanations were then given, and the prophecy made that the patient would die in three or four years. The following day an insurance of \$20,000 was placed on the life of the patient. Three years after, the brother pocketed the amount. In Germany, a medical officer of a railway corporation claimed that symptoms of paretic dementia presented by a 43-year old man were only changes due to old age.

Hanot² calls attention to the dangers to which life insurance companies are exposed from this class of patients, who, as already stated, escape the diagnostic ability of the average insurance company's physician, who is worthless in the detection of this psychosis.

Is the insurance effected on the life of a paretic dement, by himself or his relatives, in good faith, binding on the company making such assurance? The Supreme Court of Iowa has decided that persons of unsound mind are to be held bound by an executed contract or conveyance where the transaction is fair and reasonable, and in the ordinary course of business, and where the mental condition of the party is unknown to the second part, and the parties cannot be placed *in status quo ante*. The converse of this necessarily follows. A paretic dement cannot be guilty of fraud, for fraud implies a knowledge of the true state of things, and of such knowledge the paretic dement is destitute. A paretic dement effects an assurance on his life because of his psychosis. If contracts with the insane, under the circumstances mentioned by the Iowa decision, are binding, then his policies are binding on the company. If the policies were binding on the companies, no suicide by him could vitiate them. It may be admitted that, even assuming the truth of all the circumstances, it was an injustice to burden the companies with the results of the actions of an insane man. With the consequences of a law a judge has nothing to do; his duty is to declare what that law is, and the same holds good of a scientist and scientific truth. The companies were themselves to blame for accepting such a risk—a risk offered by the would-be policy holder in good faith. It may seem hard on the companies, but it would also be hard on the family of paretic demented if they should be deprived of the provision made for them. The life insurance companies use all means to detect fraud and to ascertain the value of risks. If such means prove insufficient, not through fraud of the policy holder, but through the incapacity of the company's agents, the company should be held responsible.

Another aspect of the case presents itself. If

a paretic dement insured his life, and then, with a paretic idea of smartness, committed suicide to compel the company to suffer for some imagined affront, or with the vague idea of making money for his friends, would this act vitiate his policy? Under the Iowa decision, I believe not. Legally, I believe the policy could not be declared void, however seemingly unjust its non-voidance, or rather the full requirement of all its provisions, under the circumstances, would be. The question simply resolves itself into this: Can a contract which *per se* involves an element of risk, all means of diminishing which risk are supposed to be taken by one of the persons making the contract, be regarded as void because, without fraud on the part of the other party to the contract, the risk proves greater than was anticipated? Life insurance contracts are based on the theory that the company ascertain the exact condition as regards disease. If the insured have an ordinary physical disease unknown to himself and the examiner, and die from such disease, the company is held bound to pay the amount of the policy. It would seem that the same rule should hold good in the case of a paretic dement. Though stockholders suffer unjustly in case of paretic demented from the inventive stupidity of agents and medical officers, yet their own negligence has been the cause of this loss. In the case of the two brothers cited by Legrande du Saulle, fraudulent intent was clearly evident, and probably that policy could have been set aside.

MEDICO-LEGAL INVESTIGATION OF DEATHS BY VIOLENCE IN MASSACHUSETTS.

Read before the Section on Medical Jurisprudence and Neurology at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY SILAS D. PRESBERY, M.D.,

OF TAUNTON, MASS.

In 1877 the Legislature of Massachusetts passed "An Act to abolish the office of coroner and to provide for medical examinations and inquests in cases of death by violence." By the terms of this act the county commissioners in each county, except that of Suffolk, were called upon to "divide their several counties into suitable districts for the appointment of one medical examiner in each district;" and such examiner, while appointed from a district, has the power to exercise his function in any part of the county of which his district is a portion. In practice, however, an examiner does not act in the district of another except in case of absence or disability of the latter. Examiners hold office for seven years and are appointed by the governor by and with the advice of the council.

The thirteen counties were divided into 68

² Annales d'Hygiene, 1884.

districts, according to the distribution of centres of population in each county. The usual number of districts is four, but some counties have more and some less than that number. Each examiner is sworn and gives bonds with sureties in the sum of \$5,000 to the treasurer of the county conditioned for the faithful performance of the duties of his office. Every medical examiner is required annually, on or before the first day of March, to transmit to the secretary of the commonwealth certified copies of the records of all deaths which have occurred during the previous year, the cause and manner of which he has officially investigated. For this purpose blank books for records and blank forms for returns are supplied to each examiner. A small fee is allowed and paid by the commonwealth for these returns as is done for the returns of births. These returns are bound and indexed, and preserved for reference, and from them are prepared and published by the secretary of the commonwealth such tabular results as will render them of practical utility.

The work of the examiner may be best studied under the following heads: 1. Notification; 2. View; 3. Autopsy; 4. Records; 5. Fees.

1. Notification. Examinations under this law are made "upon the view of the dead bodies of such persons only as are supposed to have come to their death by violence," and "whenever a medical examiner has notice that there has been found or is lying in his county, the dead body of a person who is supposed to have come to his death by violence, he shall forthwith repair to the place where such body lies and take charge of the same."

There is nothing in the law to indicate what shall constitute official notice, nor to show who has authority to give such notice. According to the theory and practice, any responsible person has such authority, and the intent of the law, it is to be presumed, was to allow the broadest liberty in the notification. As a matter of fact the calls usually come through the police in cities, the selectmen or their representatives in towns, the officers of corporations, the undertakers, some member of the family of the deceased, the person finding a body, or possibly, though not frequently, notice may be given by some neighbor or enemy even of the deceased, who is inclined to be suspicious or desirous of settling some old score by instituting investigation. The last motive is rarely successful, since almost without exception the services of the examiner are welcomed by the unfortunate family.

The question, shall an examiner ever refuse to make a view, has been discussed by the examiners, and the general opinion is that he should not refuse, unless there has been a misapprehension of the condition under which he is required to exercise his functions. It is not sufficient to

say that one died without medical attendance, but the idea of suspected violence must enter into the case. The boards of health of cities and towns are authorized to give certificates of the cause of death in cases of uncertified deaths, not suspected of violence. Not infrequently the examiner is consulted by undertakers, sometimes by town officers, to learn whether a certain dead body should be the subject of official view, and the answer turns entirely upon the question of the possibility of any one supposing that the death may have been caused by violence. If there be such a reasonable possibility, it is undoubtedly a case for view.

2. View. Having been notified, the examiner is required by law forthwith to repair to the place where the body lies and to take charge of the same. He now makes a careful view of the body, with such accuracy as to enable him to say whether or not the body shows any marks of violence, and especially any marks sufficient to indicate the cause of death. For this purpose the usual custom is to have the body entirely naked and to make careful inspection of every part. He also makes personal inquiry into the cause and manner of the death, if any one can be found who can give information. Under some circumstances a careful investigation of the surroundings of the body becomes important evidence in the investigation. All the facts learned in this search are to be accurately recorded.

If upon this view and inquiry the examiner is convinced that the death was not caused by violence, he will deliver the custody of the body to the friends of the deceased, if there be such. In case the body is not claimed, or is unidentified, it is to be kept in his custody for forty eight hours and then delivered to the overseers of the poor of the city or town wherein it is found lying. In case the body is not identified, a careful description of the deceased is to be made. The examiner next is to certify to the clerk or registrar of deaths the name or description of the deceased, together with cause and manner by and in which he came to his death. And here the investigation may end.

If, on the other hand, the examiner is convinced that the death was caused by violence, and he is able to determine without further examination, the cause and manner of death, he will certify as before to the registrar, and also notify the district attorney and a justice of the district, police or municipal court for the district or city in which the body lies, that there has been within the district a death by violence in the meaning of the law.

3. Autopsy. If the examiner is unable to determine satisfactorily the cause of death without autopsy, and he deems a further examination necessary, he shall so report to the district attorney or to the mayor or to the selectmen of the

district, city or town where such body lies. Any of these officers may authorize him in writing to make an autopsy, but he can make no autopsy officially without such authority. Before proceeding to make an autopsy he shall employ two or more discreet persons, one or more of whom may be physicians, and he shall first call their attention to the position and appearance of the body, and in their presence he shall make an autopsy of sufficient thoroughness to fully establish the cause of death, or to establish the fact that the cause can not be learned by autopsy. The examiner, if he deems it necessary, may employ a chemist to aid in the examination of the body, or of substances supposed to have caused or contributed to the death. The examiner, or a clerk whom he may employ, shall reduce to writing at the time of the autopsy any fact or circumstance tending to show the condition of the body and the cause and manner of death, together with the names and addresses of the witnesses, which record the examiner shall subscribe, and which is known as the record of the autopsy. A duly attested copy of the record is filed with the district attorney, and another with the justice of the district court, together with a certificate of a death by violence above described.

If, however, an examiner is of the opinion that a death was not caused by violence, and the district attorney or attorney general is of a contrary opinion, either the district attorney or the attorney general may, notwithstanding such an opinion, direct an inquest to be held in accordance with the provisions of the law, at which inquest he or some person designated by him shall be present and examine all the witnesses.

Since the action and opinion of the medical examiner turns wholly upon the question of violence, it becomes very desirable that the term violence be exactly defined, and yet, as in the case of notification, the law not only does not define it, but seems to use it in its broadest sense, if not indeed in differing senses. But since it is the object of the investigation to learn if any other person than the deceased has been either directly or indirectly causative of the death, it is fair to consider that the violence, which is to be officially reported, is a violence that may have been contributed to by the act or by the neglect of another. All cases of death by accident upon a railroad are, by special provision, to be reported for inquest, and the district attorney or attorney general may, if he deem it necessary or expedient, direct an inquest to be held in the case of any other casualty from which the death of a person results.

5. Fees. In the county of Suffolk, the examiners are paid annual salaries for all services performed. In all other parts of the State the examiners are paid fees as follows: For a view

without autopsy, five dollars; for a view and autopsy, thirty dollars; and for travel, at the rate of ten cents a mile to and from the place of view. The bills for the services are rendered quarterly to the county commissioners, who certify their correctness, when the fees are paid by the county treasurer. In case of autopsy, however, there must accompany the bill the certificate of the mayor or selectmen who authorized the autopsy, and a statement from the district attorney certifying that the autopsy was in his opinion necessary. In order to enable the district attorney to make this certificate, the examiner is required in every such case to file with the attorney together with his report of the autopsy an account of his view and personal inquiry in the case, and shall certify that in his opinion, the cause and manner of death could not be ascertained by view and inquiry, and that an autopsy was necessary for that purpose.

At this point the official relation of the examiner as such ceases, though he may or may not be employed as a witness at the inquest, or at the subsequent trial, if one follows.

Inquest. In case the examiner has notified, as above described, the justice of the district court that there has been a death by violence, the justice is required to hold an inquest, and is allowed no discretion in the matter except as to time and place of such inquest. At this hearing such witnesses as have been found to have any knowledge of the facts are summoned to testify, and the district attorney or some person designated by him may attend the inquest and examine all witnesses. In practice, the judge himself usually examines the witnesses.

After hearing the testimony the justice is required to draw up and sign a report in which he shall certify when, where, and by what means the person deceased came to his death; and if it appears that his death resulted wholly or in part from the unlawful act of any other person or persons, he shall further state the name or names of such person or persons, if known to him, and he shall file such report with the records of the superior court in the county wherein the inquest is held. The law further allows the justice to bind over such witnesses as he may think best, and requires him to take the necessary steps for the apprehension of any person or persons charged in his report with the commission of an offense.

Thus I have endeavored to describe to you the method of a medico-legal investigation of deaths by violence that has been practiced in Massachusetts since the abolition of the office of coroner, and naturally the question may arise, what has been gained by this change? In answer I will call your attention to a few of the points of gain. First, the expense, which to many minds is of first importance in matters of public concern, has been

diminished about one-third. Second, promptness in action and exactness in investigation have been accomplished. Third, all the facts of the case from the first discovery of the body to the finding of the justice are matters of accurate record and are material as evidence in the higher courts in case a trial follows the inquest. Fourth, the duties are now so divided that the man of medical training investigates so much of the case and only so much as has to do with the medical question of the cause and manner of the death, while the man of legal training settles the question of responsibility and determines whether or not a crime has been committed, what the nature of that crime, and, if possible, who is the suspected criminal. Fifth, the records in the hands of the secretary of the commonwealth constitute a valuable body of observed facts that may become of great value to the student of legal medicine. Last, the association of Medical Examiners, constituting the Massachusetts Medico Legal Society, has stimulated each examiner to keep himself well-informed and as far as possible prepared for any case that may fall to his lot. And in general, the diffusion through the State of a number of physicians specially interested in medico-legal research has tended to call the attention of physicians to that branch of medical study, and has had an influence to improve the grade of medical testimony in the courts of the commonwealth.

ETHER INEBRIETY.

Read in the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY NORMAN KERR, M.D., F.L.S.,
OF LONDON, ENG.

PRESIDENT SOCIETY FOR THE STUDY OF INEBRIETY; CHAIRMAN
BRITISH MEDICAL ASSOCIATION, INEBRIATES' LEGISLATION
COMMITTEE; CONSULTING PHYSICIAN, DALRYMPLE HOME.

Ireland has in the nineteenth century presented to the world two interesting and remarkable series of inebrio-psychological phenomena. In 1838, a simple-minded Roman Catholic priest, Father Mathew, adopted and began to advocate the practice of abstinence from all intoxicating drinks. So amazing was the impression made by him that, in three years, the roll of the teetotal pledges which he had administered exceeded 5,000,000, in Ireland, in addition to large numbers in England, Scotland and America. The reality of this epidemic of temperance was attested by the statement of the Chief Secretary, in 1840 that "the duties of the military and police in Ireland are now almost entirely confined to keeping the ground clear for the operation of Father Mathew." Though this great wave of sobriety has gradually receded, till now the extent of drinking in Erin is simply terrible. I am every now and again meeting professionally

with sons and daughters of Hibernia, who glory in their steadfastness to the pledge which they so long ago took at the hands of the Irish apostle of temperance. An accurate study of this unique crusade would, in psychological results, amply repay the labors of any earnest student of mental science.

Curious to relate, the other series of inebrio-psychological phenomena is an experience in an opposite direction—an experiment, so to speak, not, as in the former case, in temperance, but in intemperance.

ETHER INEBRIETY.

The disease of inebriety or narcomania (a mania for intoxication by any kind of narcotic or anæsthetic), may, besides other phases, assume a form correspondent to the particular inebriating substance. It may, therefore, be interesting to glance at the origin and growth of this new mode of inebriate indulgence, as this is the first opportunity afforded to us of observing the rise and progress of such a process in a community.

RISE AND PROGRESS IN IRELAND.

The centre from which ether drinking spread was the town of Draperstown (with a population of some 300), in the southern part of the County of Londonderry. Before Father Mathew's abstinence propaganda, ether drinking was there unknown. Between 1842 and 1845 a local medical practitioner, in response to a request from a few newly-pledged abstaining converts for something the taking of which would not violate their vow, gave them a drachm of ether in water. So far as I can ascertain, this was the *fons et origo mali*. A desire for more frequent doses grew upon the ether drinkers, and the practice spread in and around Draperstown till there was a shop for the sale of ether, in one town, to every twenty-three of the population. In the session of 1855-6, an Act was passed by the British Legislature allowing spirits of wine to be used duty-free in arts and manufactures, provided it was made nasty as a drink (which the Government, in their innocence, supposed would prevent people from drinking it) by the addition of a minimum $\frac{1}{10}$ of methylated spirit. As ether prepared in this way is much cheaper than ordinary sulphuric ether, this cheap production of "methylated ether" caused the consumption to increase "by leaps and bounds." The present ether area was, from its mountainous features, a central locality for the illicit distillation of whisky. Owing to the activity of the police and the making of roads, this illicit traffic was effectually stamped out. The disappointed cheap whisky drinkers found a cheap unintoxicant in ether. Mr. H. N. Draper first called attention to Irish ether drinking in 1877 (*Medical Press and Circular*, May 30), followed

by Dr. B. W. Richardson about 1879, and by Mr. Ernest Hart in 1890.

AREA OF DISTRIBUTION.

Ether drinking was in a year or so gradually introduced from Draperstown into the neighboring town of Maghera, and soon extended its sway till it occupied an area of somewhere about 295 square miles, with a population of nearly 79,000 souls. This area may, in general terms, be said to comprise the mountainous districts, especially of Derry and Tyrone, and to some extent, of Armagh and Antrim. Cases of ether intoxication have occurred in Dublin and other parts of Ireland, in Glasgow (Scotland), in Lincolnshire in England, and I have seen several in London.

THE ETHER DRINKERS.

All the cases which I have seen in England have been persons of education and refinement, who had first been alcoholic inebriates and gradually developed into devotees of these twin poisons. Nearly all of these English cases have been females, the only males having been members of the medical profession. In Ireland, women assert the equality of the sexes by taking their fair share of this form of intemperance. Small farmers and agricultural laborers make up the bulk of the Irish ether tipplers. Workmen, too, are well to the front. But the practice is by no means confined to these classes. Members of the learned professions have their representatives. Etherists are to be found at almost all ages from puberty onwards. Sturdy Irish lads and beautiful Irish lasses, brimful of Hibernian wit, as well as "60-year olds" of both sexes, are slaves to ether drunkenness. The mother may be seen with her daughters, and maybe a neighboring Irishwoman or two, at a friendly ether "bee." The habit has become so general that small shopkeepers treat the children who have been sent to purchase some article, with a small dose of ether, and schoolmasters have detected ether on the breaths of children from 10 to 14 (or even younger), on their arrival at school. Some critics have endeavored to lay the blame of this new development of inebriety on the Roman Catholic religion. Nothing could be more unwarrantable and unfair. The disease has spread principally among Roman Catholics, simply because this is the creed of the greater part of the population. One Protestant village, Tobermore, is as bad as any other place. All my cases have been Protestants.

QUANTITY TAKEN.

The amount swallowed at a draught varies mainly with the stage of education in ether consumption. A novice will find a drachm (a teaspoonful) sufficient. Gradually the wished for effect demands an increased dose, till $\frac{1}{4}$ of an oz. may in time become the ordinary "peg" of

an accomplished drinker, to use the phraseology of Anglo-Indians. These are average quantities of a so called "moderate" drinker. More "seasoned casks" have a higher capacity, many topping off half a wineglassful as unconcernedly as an average Englishman would drink a glass of claret, or an average American a glass of champagne.

The amount of ether consumed in a day is often remarkable. A confirmed ether inebriate will take a much larger dose than any I have just enumerated, and repeat the dose three, four, five, or even six times in the twenty-four hours, when "on the spree." Indeed, in some cases, half a pint has been the regular daily allowance of constant (or habitual) inebriates. In England I have known an ether inebriate use a pint of ether by inhalation every day. In Ireland, many persons keep themselves intoxicated pretty well during the day for the sum of sixpence—taking two pennyworth at 10 o'clock, 1 o'clock and 4 o'clock. What a paradise for drunkards! Drunk three times a day for 13 cents!

HOW TAKEN.

In England, in my own practice, the majority of ether drinkers have inhaled the poison. In Ireland the universal method is drinking. By the latter mode the ether is taken "neat." Owing to an idea that ether, like whisky or brandy, should be drunk diluted with water to sheathe the virulence of the poison, the uninitiated and ignorant Englishman, when in Ireland, sometimes mixes his ether "peg" with water, "just to try the stuff, you know." Ludicrous failure awaits him, for, unlike ardent spirits, ether is but sparingly soluble in water. The pungency of ether, except to those who have "finished their education," generally calls for an "overture" to the "act" of ether swallowing. Scene I.—The mouth is washed out with cold water. Scene II.—A draught of cold water is drunk. Scene III.—The ether is swallowed "neat." Scene IV.—The performance closes with a second and final drink of cold water. The preliminary draughts of water are to cool the mouth and throat, and the post ether draught is "to keep the ether from rising." The washing of the mouth is soon omitted. By and by the preliminary draught of water follows the same fate, the ether dose and the succeeding draught of water being the commonest method. As his education advances, the etherist dispenses with water altogether. He may for a while, especially when drinking an unusually large dose, hold his nose with one hand, but probably ends by despising all precautionary safeguards, and by simply drinking his mouthful of ether at a gulp.

WHAT IS TAKEN.

Ether purus of the British Pharmacopœia was

at one time affected by my inebriate patients. This pure ether ($C_2H_5_2O$), which is free from alcohol and water, has been in my hands the only ether preparation which has proved to be without complicatory drawbacks when used as an anæsthetic (Brit. Pharmacopœia, 720; U. S., 725). Ether of the B. P. (sulphuric ether) was, however, the article generally used for purposes of intoxication. It contains 8 per cent. of alcohol and water with 92 per cent. of *ether purus*, and is soluble in all proportions with rectified spirit, but in only 1 in 10 with water. The specific gravity should be (B. P.) .735; (U. S.) .750. It is a swift, potent, diffusible stimulant, narcotic, anæsthetic and antispasmodic, of great value in medicine. It has a strong, penetrating odor, is sweetish, hot, burning and pungent to the palate.

To America the whole world owes a deep debt of gratitude for the introduction of ether as an anæsthetic by Dr. Morton, in Boston, in 1846, and any saddening misnse of this grand mode of alleviating human suffering ought not to lessen our appreciation of this splendid boon to humanity.

By the Act 18 and 19 Vict., c. 37 (1855-6) the use of spirit of wine, free of duty, was permitted in the arts and manufactures, on the addition of a minimum of $\frac{1}{5}$ of wood-naphtha (methylic alcohol or spirit from the destructive distillation of wood, after rectification; specific gravity .803 B. P.), with a view to prevent this fouled liquid from being drunk as a beverage. Ether prepared from this fouled duty-free spirit is, of course, much cheaper than ether prepared from spirit of wine on which duty has to be paid. The intention, however, was defeated, inasmuch as in the process of manufacture of ether from the fouled spirit, the fouling ingredients (*i. e.*, the methyl products) are destroyed. Thus, contrary to the general belief in what is commonly called "methylated ether" being as nasty as the methylated spirit which is used for lamps and for polishing purposes, "methylated ether" is to the taste hardly discernible from pure sulphuric ether. This so-called "methylated ether" is practically undistinguishable from *ether* (B. P.) at the specific gravity of .717, *i. e.*, when purified. At any other specific gravity, an odor is given off after evaporation. Practically, one cannot discriminate between the ethylic and methylic productions.

Price.—The ether thus prepared from the duty-free spirit (sp. vin. rect. *cum* methylic alcohol), can be produced at as low as one-seventh of the cost of ether prepared from the duty-paid spirit, the latter being bought wholesale at \$1.25 per lb., and the former at as low as 16 cents.

HOW PROCURED.

Ether is imported mostly from England, partly from Scotland, by larger chemists and druggists

in the principal towns of Cookstown, Maghera-felt, and Maghera. The large dealers supply small shopkeepers, and also cottagers, who sell in "draughts" (rather less than 2 teaspoonfuls) for one penny. The small shopkeepers also supply the hawkers (who are very often women), who attend fairs and other festive gatherings to dispense the "draughts" of the liquid poison. These "draughts" are also to be had from the surgeries of some medical practitioners, and in cottages or ether shebeen, where the cottager keeps a pig or two, and sells ether, the country people frequently giving potatoes, meal, or other produce in exchange. The hawkers carry about a bottle of ether, and do not scruple at selling to any one, however young, bartering a little for one or two eggs. In this way the children may procure the ether on their way to school.

ETHER PHENOMENA.

Intoxication by ether presents one distinguishing feature as compared with alcoholic intoxication. The phenomena are practically alike, but in rapidity of manifestation, alcohol is "nowhere." Indeed, in this respect, ether beats the record. There is the exhilarative stage of morbid exaltation, when the fun and exuberant merriment, the latent and ineradicable impulse of one "spoiling for a fight" of the genuine Irishman stands revealed in the twinkle of the eye, and the flourish of the shillelagh. The pleasing but quickly vanishing whirl of enjoyment is followed by an evanescent episode of brain disturbance and mental riot, with muscular paralysis and incoördination. To these succeeds the concluding comatose stage, when the patient is said to be "dead drunk." The shortest period in which I have seen this inebriate panorama move on till it swung round to recovered sobriety has, with alcohol, been six hours. With ether, I have witnessed the entire revolution in less than two hours.

In my observation an alcoholic inebriate career, from start to a fatal finish, has in America been, on an average, one-third of the duration of a corresponding career in Britain. So, curious to say, has the length of an ether intoxicative paroxysm been one-third the length of an alcoholic intoxicative paroxysm. Thus the etherist can have three thorough "drunks" for one of the alcoholist. Herein, in addition to the greater cheapness, lies the superior claim of ether to the "greedy for intoxication," the true "narcomaniac."

Intoxication by ether may be described as "hysterical," and intoxication by ether *cum* alcohol as "maniacal." A man arrested while drunk on ether alone, would probably be quite sober by the time the constable had him at the police station, which might be very awkward for the constable, though the arrest had been made

when the man was in a frenzy of boisterous excitement. Several deaths from ether, and ether *cum* alcohol, have occurred.

PATHOLOGY.

Little is known of the pathology of ether. The habit has been too young to afford opportunities of much post mortem examination of ether inebriates. Premature old age, an antedated shriveling up of the living frame, attests the poisonous influence of the destroying agent. Gastritis (acute and chronic), debility, dyspeptic distress, epigastric pain, pallor, tremors, timidity, moroseness, suspicion, nervous prostration, chilliness, a cyanosed or lemon skin, and an intermitting heart beat, with exaggerated reflexes, are prominent symptoms. I have one such victim in my mind's eye now. Fawning, cunning, terror-stricken, this wretched medical colleague is the incarnation of utter misery. Not yet 40 years of age, he shuffles about like a worn-out old man of 90 after a wasted and mis-spent life. It has been urged by some medical authorities that ether is guiltless of producing any pathological lesion, from the almost lightning rapidity with which its inebriating manifestations appear and fade away, and from no serious morbid after-death appearances having been observed. This conclusion is, in my judgment, premature. Judging from the symptoms from which I have seen ether inebriates suffer, I have not the slightest doubt that ether has a pathological influence on various organs and tissues, and that, if ether drinking could boast of as venerable an antiquity as alcohol drinking, unmistakable lesions would have been but too manifest. What are the forty years of ether consumption by a hundred thousand persons, to the thousands of years of alcohol consumption by at least as many millions of human beings?

REMEDIES.

Happily, this new form of inebriation is but in its infancy, so there is some hope that its growth may be "nipped in the bud." As, in the conversion of methylated spirit into ether, the nauseous methyl products are destroyed, something might be done towards making the liquor loathsome to the palate by the compulsory addition of the wood spirit *after* the completion of the etherification, before the sale of the liquid. This, however, would be but a palliative, for I have had patients under my care who drank methylated spirit (some even from jars with anatomical preparations), and, in Edinburgh and Glasgow, Sunday drinking of this nasty beverage recently flourished apace. In a certain locality in the north of Ireland, the drinking of methylated spirit was introduced seven or eight years ago. At first confined to the very poor in a hilly district, it has spread rapidly, till now

farm laborers and farmers are daily indulging in it.

There are many inebriates who hate and abhor the taste of the intoxicant which, in their narcomaniac madness, they would barter their salvation to procure.

Another remedy would be the abolition of the retail sale. This would help by putting difficulties in the way of the drinker, but would only mitigate the mischief. Still more effectual would be the scheduling of ether as a poison, the sale of which is restricted to druggists under certain safeguards. This course was so readily adopted for Ireland by the British Government in January last, that I have yet hope the day will come when the more deadly allied poison—alcohol—will be placed in the same category, and so dangerous a drug will be relegated to the shelf of the apothecary, its sale hedged in with as stringent precautions as is now the sale of arsenic or prussic acid. But this halcyon era of prohibition will only be attained after a prolonged struggle, amid the howls and groans of an enraged liquorism, whose indignation is concentrated on all who attempt to "rob a poor man of his beer."

It is too soon yet to foretell the ultimate result of the bold step taken by our Government in scheduling ether as a poison, but it has made the procuring of ether for drinking purposes so difficult that for the present the sale has diminished by at least 75 per cent. I fear, however, that the cupidity of some wholesale dealers will incite them to risk the penalties of the law by surreptitious sales, which will speedily be ferreted out by the marvelous cunning of the diseased and demoralized inebriate.

The lines of sound treatment of ether inebriety, and of its prevention by law, must alike be based on an intelligent appreciation of the true character and etiology of ether drunkenness. This is, in reality, but a new manifestation of an underlying morbid condition which renders certain of the sons and daughters of men peculiarly liable to plunge into intoxication. We can never hope to succeed in the cure and prevention of any disease, until we first recognize the presence of the disease itself. The malady of narcomania, as subtle as it is far-reaching in its influence on body, brain and mind, and morals, is a legitimate outcome of natural law, and we will not be adequately equipped for the fight till we are thoroughly conversant with the laws under which every form of the disease of inebriety is developed and propagated.

A NEW REMEDY FOR WHOOPING-COUGH is onabaine, in doses of about $\frac{1}{1000}$ grain. It has been tried with success by Dr. Gemmell, of Glasgow, and lately by Dr. I. L. Porteus, of Yonkers, N. Y.—*New York Med. Journal.* •

SYNOPSIS OF OPIUM INEBRIETY; EFFECT, NEEDED LEGISLATION, DISTINCTIVE PLANS OF TREATMENT NECESSARY FOR THE SUCCESSFUL CURE.

Read before the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY W. S. WATSON, M.D.,

OF MATTEAWAN, NEW YORK.

Member of the American Association for the Study and Cure of Inebriety, of the Ninth International Medical Congress, of the American Medical Association, Dutchess County Medical Association.

He who has proven himself an attentive observer of the transactions of man for the past twenty-five years, does not hesitate to pronounce the last quarter of the transpired portion of the nineteenth century the most remarkable in the history of man. The philosopher, the scholar and the philanthropist, will be ready to declare that at no period, in all former times, have the intellectual energies of our race made so momentous discoveries, or put forth such exalted plans of benevolence for the benefit of mankind. The mighty achievements in the mechanical world have given new impetus to old powers and created new ones of vast results, profitable to us as a nation and as individuals. Revelations in language, in inscriptions, in customs and laws of nations have unfolded treasures of undoubted excellence and worth, important in history, and eminently subservient to profound and philosophical investigation of man; while the knowledge now possessed of Nature and her laws, has enlarged the domain of humanity with results of vital importance. Learning is necessarily no longer confined to the favored few, nor is wisdom locked up from those earnestly seeking. Like the rays of the noon-day sun, intellectual light beams forth from almost every countenance; instruction is easily acquired by almost every individual; knowledge unfolds herself to every inquirer. Man is more and more aware of his capabilities. Onward, is the watchword, Progress, the spirit of the times. This is an age of investigation; the relation of cause and effect is sought; mind penetrates everything, theories of the past are being submitted to a more searching inquiry in the crucible of the present, new truths are evolved, old ones confirmed; error and prejudice vanish before the judgment of this enlightened age; we live in an epoch full of change, alive with conflicting opinions. Need we wonder at an obtuseness in the public mind in regard to the legitimate claims of the medical profession, a want of discrimination in recognizing the genuine, or an absence of veneration for the dictates of experience? It has been hinted already that the spirit of the age is one of reform. In social institutions, in jurisprudence, in our criminal legislation, and political economy,

leading minds are ardently at work advancing new theories; should not the same principle be made evident in our profession? Should so vital a thing as that of the public health be neglected, is it well that we look on with unconscious indifference at the warfare that is being waged on the life and health of untold thousands by charlatans and imposters, who vaunt their so-called cures broadcast through the medium of the press? The newspapers and periodicals are filled with advertisements skillfully designed to extort money from victims of the opium, morphia and chloral habit; you cannot pick up a paper, be it a religious or not, that does not contain their advertisements. How a Christian paper or journal can be a party to such a crime as that of helping these unscrupulous fiends to make capital out of the unfortunates that are addicted to the use of such drugs, is more than we are able to comprehend; the money to be realized from advertising for such imposters seems to crowd out all sense of right, hence the only way to overcome this evil is to enact such laws as will make it a criminal offense, punishable by imprisonment, to offer for sale any mixture or compound for the cure of inebriety, opium or alcoholic, into which composition opium or alcohol enter, or for being a party to the sale of such drug or compound, by advertising it or otherwise. Until such a law is in effect through the United States, opium, alcohol, and inebriety will hardly have a cure; there is no question but thousands are made mad by the vile stuff that is offered as cures for the opium and alcohol habit; if the compound of itself does no actual harm by reason of any powerful constituent, the disappointment, the blasted hopes that were so elegantly colored up by the advocates of the so-called cures is enough to set one crazy when he learns that his habit has only been fed. Legislation, and legislation alone can reach this specie of fraud, once it is made a felonious act to sell or offer for sale, or advertise for sale any nostrum or compound until an analysis has been made by the State Analyst, and his certificate is attached thereto certifying that said compound does not contain any drug or combination of drugs that are known to enslave. Opium addiction: Is it on the increase? It may be said that opium inebriety is a disease of modern life, or recent origin. Opium eating, as it is called, has been practiced for centuries in the East; in China almost one-fifth of the entire population are addicted. Opium eating and smoking, strictly speaking, never prevailed to any great extent among Western nations until after the discovery of morphine in 1817. Since morphine has come to light it has made thousands of victims; especially has the habit increased with alarming rapidity since the hypodermic syringe came into use. To day, opium, in some of its forms, holds in bonds hundreds of thousands, yes millions of

the human race. We believe that there is no habit that is more pernicious to us, as a people or nation, than that of opium inebriety, for it takes possession more insidiously and holds on more tenaciously than any other known drug. The amount of opium coming through our United States Custom Houses, as reported, does not show an increase in the consumption of opium, during the past eight or ten years. There being no increase of imports does not conclusively show that no more opium is being consumed; legislation, increase of duty, has not shut out the supply. Some years ago Congress imposed a duty of ten dollars a pound on opium, with the hope that such duty would cause a decrease in the consumption of the drug; the effect has been an opposite one. The increase in price has been the means of a large amount of smuggling through various channels, the profits being enormous. Some statistician has calculated that the gains of English opium merchants in the last half century, exceeds two thousand million dollars. Large financial interests are concerned in fostering the opium vice in the United States, and here as well as in England fortunes are being made, by evading the tax imposed. We imported, and there was passed through the custom house, according to statistics of the Treasury Department, as follows:

In 1884, crude opium, 9 per cent. morphia, 264,746.15 lbs., for smoking 1,66,600 lbs., morphine 27,850.18 ounces.

In 1885, 351,609.15 lbs. crude opium containing 9 per cent. morphia, morphine 20,709.50 ounces.

In 1886, 351,193.11 lbs. crude opium containing 9 per cent. morphia, morphine 17,731.47 ounces.

In 1887, 468,153.13 lbs. crude opium containing 9 per cent. morphia, morphine, 14,431.00 ounces.

In 1890, 380,621.42 lbs. crude opium containing 9 per cent. morphia, morphine, 19,953.60 ounces.

It is estimated that during the year 1889 alone, there was something over 800,000 pounds of smoking opium alone smuggled into the United States, and there is every reason to believe that the amount smuggled in is perhaps double, when we consider the fact that every month three or more steamers arrive from China, at the western terminus of the Canadian Pacific Railway, at Vancouvers, most of them having opium on board. An average cargo, it is said, is about 25,000 pounds; a small amount may be retained for consumption in Canada, the remainder, it is said, is smuggled into the United States.

EFFECTS OF OPIUM.

There is a vast difference between individuals, not only as regards tolerance of such a poison,

but also as regards the forming of the habit; some temperaments fall almost immediately into the habit, others can use opiates for years and seem as free as though habit was an impossibility; we will, however, find victims among all classes. Morpho-maniacs include many of our literary men, mathematicians and scientists; medical men are more exposed to the formation of the habit than any other class. There is in his case what might almost be called a reasonable excuse for something which will quickly give relief from pain, if attacked, knowing as he does the undoubted effect of morphia to relieve pain; in his hurry, while others are calling upon him to help them, he may and often does insert or take a dose of an opiate. Business and urgent calls give him no time to consider his own case, or how often he has resorted to the remedy, and presently he finds he cannot throw off the craving, a need is implanted almost without his suspecting it. Thus thousands of physicians are made slaves to the opium habit, from which they cannot free themselves unaided, for he is himself no more, all is abnormal. The normal state with an opiumiac is given in a few words: the will is paralyzed, his personality is destroyed. The opium habit is one difficult of eradication, the percentage of reformed drunkards is greater than that of opium inebriety; the drug opium long used becomes a necessity, and if withheld the whole system, every cell, cries out in agony, harmony of function can no longer be maintained without opium, the whole organism has been adjusted to the new or artificial condition in which the elements of equilibrium are in the poisonous drug. A sudden failure to supply the stimuli gives rise to an overwhelming craving, and plunges the individual into a trying ordeal from which there is no relief unaided, except it be by repetition of the poison and in increased doses. It has often been said by those having passed the trial of abstinence, that no one else but such can tell or give the faintest idea of the suffering one experiences when trying to abstain, without having been prepared for such withdrawal; against their better judgment they are driven to madness, and as a rule they seek relief by returning to the accustomed drug. It matters not who he may be, whether of the high or low, or of what caste, he finds he is indeed a slave to a habit over which he has no longer control; self control is a lost factor with him. Opium inebriates tell us but one story, that they are no longer free. Opium inebriety is truly a disease; there is brought about certain molecular changes, and a neurosis is produced amounting to a necessity for the continuance of the drug, until a preparatory stage is passed, during which sedative drugs are used and the system thoroughly aroused, reflex sensibility, or disturbances anticipated by such medication as will displace and tone up the par-

alyzed functions. The mental faculties are among the first that suffer from the use of opium, as melancholia, hallucinations, especially of sight and of dread; sometimes the opposite is the case, instead of sadness or depression, there is excitement or mania, vertigo is common; with some insomnia is of frequent occurrence, perhaps wakeful all night and sleepy during the day. Sensation is generally impaired or perverted, in most cases there is a state of anaesthesia which largely accounts for the painless punctures with the syringe; upon the digestive organs morphia exercises, sometimes, a peculiar influence, if administered hypodermically it sometimes develops an appetite for a time, when if taken by the stomach, it destroys all desire for food, and not infrequently brings about nausea and vomiting; upon the bowels, the paralyzing effect is marked, a large proportion of persons are obstinately constipated while they continue its use, abstinence brings about diarrhoea; many patients are also troubled with dysurea, and only pass a few drops at a time, the kidneys seem to be paralyzed and do not perform their functions well; general nutrition suffers from the paralyzing influence. Those addicted to opium grow old fast, their eyes grow dull, face is without expression, skin becomes yellow and generally greasy.

Abstinence, there is a state of disquiet, an uneasiness, a state of agitation comes over the individual if his dose is long deferred and the system is long deprived of the stimulant, a sense of discomfort takes hold and he is restless and irritable. The highest effects of the abuse of opium are developed in the abstainer; among the marked symptoms are diarrhoea which can always be expected if the opiate is suddenly withdrawn, and if it does not come on, the patient should be watched, for he is probably deceiving you, shamming.

DIAGNOSIS.

You are generally struck by the strange appearance and expression of this class of people, the wan complexion, the vacant look together with a dulness, listlessness, with marked lowering of the physical as well as moral status, functions of nutrition are profoundly affected, with generally a loss of appetite and obstinate constipation; the most reliable method of diagnosis, and one that does not require acknowledgment on the part of the patient, is the examination of the urine; morphia is eliminated by the kidneys and can be found in the urine, and when found you are absolutely certain that the habit exists. Examination from day to day is a part of my method for the detection of deceit on the part of the patient; of course it must be taken into account that the alkaloids of opium are not all eliminated for some eight, or possibly ten days after commencing to abstain; by analysis of

the urine we have a certain means of knowing the condition of our patient.

TREATMENT, DISTINCTIVE PLANS.

There are some three or more plans or methods. First is the abrupt withdrawal or suppression, practiced by the somewhat noted German, Dr. Livinstine, and by many others after him. The plan is simply to take away the drug at once, without any preparation whatever. In regard as to dose; experience has taught thousands that the use of morphia or opium can not be suddenly stopped without serious results following. The abrupt withdrawal entails much suffering of mind and body and a risk of suicidal ending. Collapse is threatened on every hand; such a method is barbarous, uncalled for and inhuman; any one subjecting a person to such cruelties should be held for malpractice. Dr. J. B. Mattison, of Brooklyn, one of our ablest American writers, a man of considerable experience in this line has, upon several occasions, expressed himself as bitterly opposed to the abrupt withdrawal, and holds that no man is warranted in subjecting his patient to such torturing ordeals. We are aware that the Livinstine method has its advocates even to day, and some are high in the profession; we are of the opinion of Professor Bartholow, when he says one such an experience and he could not be induced to repeat it, if for no other reason than strictly humanitarian reasons, since the mental and physical sufferings are truly horrible. The dread of untold sufferings that one has to undergo keeps hundreds under the yoke of habit; the impression is broadcast over the land that to quit it is to entail upon themselves tortures beyond the endurance of almost any ordinary person. A second method is the rapid withdrawal, but not abrupt. Dr. Mattison advocates this method and it is generally a safe one to pursue. The plan consists of first producing a certain amount of sedation or control of the reflex irritation present. Dr. Mattison, in his monograph on the treatment of opium addiction, says the use of sodii bromide is, so far as he is aware, original with him in connection with the treatment of the opium reflex irritability; we have found in it the safest and most valuable sedative in such cases, for many years, our attention being first called to the effect of bromide of sodii and its probable action in the reflex disturbances following the withdrawal of opium from the human system by the late Dr. Beard. In using bromides to counteract, and to get desirable results, it requires large doses and for some days, from four to six days. The system needs to be constantly under the influence for such a length of time as named before an attempt is made to withdraw, in other words, the maximum sedative effect of the bromide should be secured by the time the maximum nervous dis-

turbance is expected or brought about by withdrawal of the opium. The rapid withdrawal is, in some respects, the most desirable of either the three plans. Sudden, rapid or gradual, better than the first from the fact that the system is saved the severe shock of the first and the necessarily longer time of the latter, and were it not a fact that many cannot even endure without severe trial and suffering under the rapid method, I certainly would rigidly adopt such a plan, but the gradual, with me, seems to meet more constitutional conditions than either. Gradual withdrawal is the easiest plan and the one most likely to succeed in the largest percentage of cases; it is to us the most logical from the very fact the habit is gradually formed, certain conditions and changes were produced gradually, therefore, it is rational to gradually withdraw or undo.

NECESSARY MEANS TO SUCCESS.

It is indispensable that the patient place himself under care of one familiar with the work, one that has studied the conditions that are likely to arise during the period of abstinence. Opium addiction, it matters not how used, produces radical changes in the system, a neurosis is produced amounting to necessity for the continued use of the drug, the demand for opium is so imperative as to place the consumer wholly beyond the power of resistance unaided. The principal difficulty we encounter in treating those addicted to the use of opium, is that they have lost about all their will power, or self-control, in fact, confidence in themselves; they have a disease that impels an increase rather than power to diminish the doses, repeated attempts to abandon the use of opium has proved their utter inability to even diminish the dose; therefore there is but one road leading to a cure, and the only remedy or reasonable chance or plan that offers any assurance of a cure, is to place themselves under the care of a specialist in the work; in the hands of a conscientious practitioner who from contact, study and close attention to each patient's peculiar needs can best provide for every emergency, opium inebriety or eating, as it is called, is a vincible disease and curable, the person being otherwise constitutionally strong and free from organic disease, having an earnest desire to be cured; it matters little as to the extent or time used, nor need there be any dread of the hard ordeal to be passed through that has been pictured as worse than death; there are days of rational medicine, of humane and scientific methods. A special institution designed for such cases is the proper place, where appropriate arrangements are made for the care of each person, with provision for carrying out the best method for each particular case; certain symptoms and conditions have to be met promptly when they

do arise; in some instances a collapse condition threatens, which is best met by stimulants of ammonia or alcohol; in extreme cases a hypodermic dose of morphia may be a necessity for the time; delirium can be warded off by coca, chloral and bromides; if there is vomiting, omit food of solid character and give hot beef extract, hot milk, beef peptonoids (liquid form), medicine, ammonia ar. spr., bismuth sub. nit. Diarrhœa: clear out the *prima-viea* first by an emulsion of ol. ricine with spr. galci, then give bismuth sub. nit. and zinc sulph. carbolate. Pains in the legs treat by hot foot bath, massage and friction. Sleeplessness, restlessness: be sure first that your patient is not shamming, then give full doses of bromide, and sometimes ammonii valennate in the elixir form. Where sleeplessness comes without pain, I believe we have in the new drug, sulfonal, a most excellent sleep producing agent; being tasteless, is easy to administer. Sulfonal-bayer, is truly a hypnotic, in doses of from 10 to 20 grs. it does not derange the appetite or digestion, and does not seem to have any effect on the renal secretions, acts in from 1 to 3 hours and the effect lasts from 5 to 7 hours. In insomnia from pain it is of no value. From our present therapeutic knowledge of sulfonal we think it not advisable to give it in increased doses, from day to day, rather, if necessary, to give it nightly, in diminishing the doses. Codea is a preparation of opium that can be given to allay pain as safely as any of the opiates and without any great liability to formation of habit; in cases presenting an anæmic condition, iron and strychnia are proper. If any notable depression or prostration of any considerable duration, alcoholic stimulants are demanded. Restlessness and insomnia are frequently warded off by the hot bath before the hour of retiring. Electricity is useful in almost all cases and many times will tranquilize the system, especially the electric bath. Among the essentials that are positively needed, if you would succeed, is mental quietude. Opium and chloral cases need be in an atmosphere of tranquillity, away from all exciting causes; lively diversions, pleasant company are desirable; the patient should first of all select a healthful place with cheerful surroundings as practicable, and above all, place him or herself in the care of one in whom they have confidence; once in the institution no more information should be imparted as to when or how they get rid of the opiate; if the patient is one that uses the hypodermic syringe, a change must be made at once, the syringe must be discarded and all opium should be taken by the mouth.

THE College of Physicians of Philadelphia has awarded the Alvarenga Prize for 1891 to Dr. L. Duncan Bulkley, of New York, for his essay on Syphilis Insontium.

THE ABSENCE OF REASONABLE MOTIVE IN THE SO CALLED "CRIMINAL ACTS" OF THE CONFIRMED INEBRIATE.

Read before the Section of Medical Jurisprudence and Neurology, at the Forty second Annual Meeting of the American Medical Association, Washington, D. C., May 6, 1891.

BY L. D. MASON, M.D.,

CONSULTING PHYSICIAN INEBRIATES HOME, FORT HAMILTON, L. I.

"Motive" may be defined as that which actuates or influences, that which determines choice. It implies the presence of an unimpaired will power, at least one that is not so seriously impaired as to be incapable of volition, and actuated either by right or wrong desires.

Impulse is the sudden application of some powerful motive, that causes the will to act hastily without usual deliberation, or that exercise of the reasoning faculties that occurs when a purpose is deliberately formed. The genesis of impulse may be a good or evil motive.

In both instances either when the act results from the motive operating upon the mind through a deliberate and logical course of reasoning, or impulsively, as when the motive acts independently of, or supercedes and dethrones reason, if it attempts to assert itself in either instance, there is one *condition* that is common to both, and that always is present, namely, *consciousness of the act*. The person invariably knows he has performed the act whether the "motive" were good or evil, the result of deliberation or of impulse.

How often do we hear the expression, "what motive urged him to do such an act?" and if the person be in a normal mental condition the law, if the act involves a legal infringement, arrests and punishes the transgressor. But are these words applied to the acts of an insane person? Certainly not. All acknowledge that the will power in this case is held in abeyance in some instances, or permanently annulled in others in which the insanity is *incurable*. The actions of the acute or chronic insane are "senseless" and utterly devoid of reason; if a "quasi" motive is asserted it is insufficient, and as a rule ridiculous, incompetent to explain an act often involving matters of the greatest moment, even life itself. This is seen in certain forms of monomania. Thus the pyro-maniac sets fire to a crowded tenement. Gives as a reason for his motive in so doing that he likes the excitement and confusion incident to such a scene; all other motives based on rational explanation being excluded, such an one would be regarded and dealt with simply as a person possessing a dangerous monomania, and demanding close confinement in an insane asylum. No one is held responsible for his acts, if he is incapable of exercising his will power, the ability to reason from cause to effect or discrimi-

nate between good and evil courses, and the consequences resulting from these.

Even in some forms of insanity where the will power and reason are not totally annihilated, the insane person capable of exercising a discriminating power to a certain extent, having at least a partial knowledge of right and wrong. Even in these cases the insane person is never legally *punished* although he may be disciplined by "institutional forms of correction;" this treatment is much the same as a child, who has not yet arrived at the years of discretion, and is still subject to his parents; the parent may correct the evil doer of tender years, yet the law will not punish such an one.

The law recognizes this fact, the absence of full responsibility among the more youthful class of criminals, and among the "criminal insane," so-called. In the former instances the State establishes "Reformatories," in the latter, an asylum for the "Criminal Insane." But while the insane, the imbecile, the idiots, and those of tender years, have thus been leniently dealt with, by some strange, illogical process of reasoning, or by actual indifference to the facts of the case, the confirmed inebriate has been excluded from all these benefits, and moreover, his inebriety has been regarded not as an extenuating circumstance, but rather as an aggravation of his so-called criminal act.

Are his acts rational? Are they based on a reasonable motive? are they the result of a well-balanced mind? is he always even conscious of the acts he performs? Analyze the acts of the confirmed inebriate and you will find that they are the acts of an *insane person*. Insane from the temporary or habitual use of alcohol.

If we can show that in the majority of cases, in the acts of the confirmed inebriate there is absence of proper motive, absence of intelligent impulse, absence even of consciousness of the act in some instances, ought he not to come under the benefits of that unwritten or recorded law which excludes from penalty the insane or those of an irresponsible age, and does not hold them responsible for their acts?

It has been abundantly shown, particularly by the researches of Dr. T. D. Crothers, that amnesia, partial or complete, is the mental condition of the average confirmed inebriate. If the loss of memory is complete, he becomes a veritable automaton; his movements are mechanical, devoid of thought or reason, and he is therefore unconscious of his acts; under this condition what he does may be ridiculous or even dangerous. His actions are similar to those of a somnambulist who, walking in his sleep, performs deeds of which he is totally unconscious when awakened. The acts of the confirmed inebriate are thus often performed unconsciously, and when he comes out of this "trance state," so-

called, or condition of cerebral automatism, he has not any knowledge of what he has done, and yet oftentimes there is a seemingly rational action on his part, and his condition may not be detected, because not suspected, by those with whom he is brought in contact; while in this condition the inebriate may commit acts that are criminal.

Mendacity has been set down as one of the prominent characteristics of the inebriate, but I am convinced that the denial of the inebriate of the statements he has previously made or the acts he has done, when confronted with them, is often due to his utter unconsciousness of ever having made such statements or performed such acts.

The "testamentary capacity" of a confirmed inebriate should be excluded on this ground, and no "confirmed inebriate" should be empanelled in any jury, nor should his testimony as a witness be received in any court.

The validity of the signatures of confirmed inebriates, to wills, contracts, or affidavits should always be questioned if allowed, and "marriage" contracted under these conditions should be annulled. I am acquainted with an instance in which the confirmed inebriate was a young man of wealth, who contracted such a misalliance. The validity of the marriage was not questioned on the ground of the avoidance of publicity, and the woman, whose sole object was money, finally consented to relinquish her claim for the sum of twenty thousand dollars. Now I maintain that such a marriage was not valid, and would not have been recognized in legal courts.

Not only in the trance state, where consciousness seems to be annulled, and the memory temporarily abolished, may the inebriate perform acts that he is totally unconscious of as a somnambulist or automaton, and thus render himself liable to criminal procedure, or the subject of fraud on the part of others.

But there is under this condition a tendency to repeat the crime or act he may have been previously guilty of, a *monomania*, so to speak, for a special act.

Dr. Alex. Pudden of Edinburgh, reports the following cases:

At the prison of Perth, one woman was committed 137 times for being drunk, *her invariable practice was to smash windows*. A man when drunk stole nothing but bibles. Another stole nothing but shawls; another shoes. A man was transported for stealing tubs on seven different occasions; with one exception he was always guilty of tub stealing. Others have been repeatedly convicted of horse stealing.

In others the destructive tendency is marked; to pull down and destroy, unusual prodigality and waste, such as scattering money in the street, or throwing it in the fire. Such persons are notorious for "cleaning out" a saloon, smashing, break-

ing and throwing out on the street articles of furniture, etc. There is not any "reason in the madness" of these temporarily insane inebriates. Their actions are "motiveless." The whole machinery of the will is out of order, the power of coordination of the faculties is lost, hence all acts are erratic.

In addition to the "trance state" and "monomaniacal acts" of the confirmed inebriate, there is another condition under which the inebriate may perpetrate higher grades of crime. We refer to that condition where the prominent characteristic of the insanity of the inebriate, is the monomania of suspicion or persecution, a condition not uncommon in the confirmed inebriate. Under this condition the inebriate is morose, taciturn, secretive; if he communicates his suspicions to any one, it is only occasionally and with great reservation. He imagines that enemies are trying to poison him; he hears voices in the air; he is followed, and in danger of being waylaid, or his wife is unfaithful to him; suspicion of "marital infidelity" is very common in these cases. Robbery, mutilation, murder, every possible contingency that may happen to a person, are imagined by these insane inebriates, as being applied to their case.

Acting under erroneous suppositions, they prepare themselves for the imaginary danger, or assault those whom they believe would injure them; or take vengeance on the innocent wife whom they judge guilty of marital infidelity. Oftentimes their mental condition is not suspected, and oftentimes only after they have wreaked their insane fury on those about them.

And just here in parenthesis we would remark that though the acts of the *confirmed inebriate* may fill every grade of crime, from petty theft to homicide, yet those criminal acts which call for shrewdness, mechanical skill, involving as they do the maturing of long continued plans, well laid, and aptly executed, as professional burglary, systematic forgery, etc., the confirmed inebriate is incapable of.

The burglar and the systematic forger may drink liquor, but they have the fullest exercise of their mental faculties, and the ability to use liquor moderately, so that their hand is steady, their nerves unflinching, and their reason unclouded. This is the universal testimony of the governors or wardens of penitentiaries and prisons in America and Great Britain, and hence is the great distinction between the so-called "criminal inebriate" over the professional criminal. The confirmed inebriate acts without motive, without the deliberation, without that usual caution and concealment that characterizes the criminal who is in a normal mental and physical condition.

Hence the insane inebriate, the subject of the monomania of suspicion or persecution, is easily

traced to the act committed by him, and his attempts at concealment, if made at all, are illy disguised. He is not an assassin, striking from the shadow and then disappearing. His acts are often in the open day and the most conspicuous public places.

Let me cite a prominent example or so that may more forcibly illustrate this class of insane inebriates. And these cases will also partially illustrate the acts of the inebriate epileptic—different only in this, that the prodromata or period of incubation is longer in the inebriate having the monomania of suspicion or persecution, than in the epileptic inebriate. In the latter, the act occurs as the coma following the convulsion had passed off. The latter class are the most dangerous of all insane inebriates, for they add to the insanity of epilepsy, that also which alcohol begets. The following cases are instances where the characteristic type of the insanity of the inebriate was the "monomania of persecution" or of suspicion.

Case 1.—"The patient is 43 years of age, has been drinking to excess for several years past, is insane. The insanity is the direct result of his excessive use of alcohol—there is not any hereditary taint. His insanity lasted about a year; he recovered and resumed his business, only to relapse, and is now drinking harder than ever. The immediate cause of his relapse was a sprained ankle, from which he suffered very much. His insanity at all times is that of the 'monomania of suspicion' or 'persecution.' His suspicions are mainly directed towards his wife and child. He walks about the house, and if he had his full liberty, would no doubt assault them, for it was found before his condition was fully ascertained, that he had concealed, under the stationary washstand of the bedroom occupied by himself and his wife, a dirk knife, which was covered with some old clothes." (Reported by Dr. I. E. Lester, *Journal of Inebriety*, Vol. vi, p. 32.)

The following case was reported by Dr. Drake, of Cincinnati, O., and was published in the report of the New York State Inebriate Asylum for 1866, the late Dr. I. E. Turner, Superintendent. At the time of the occurrence, it attracted the attention of the medical public in its bearing on the legal responsibility of the insane.

"John Birdsall, of Harrison, in that State, was indicted in 1829 for the murder of his wife with an ax, by dividing the spinal column in the neck. He was about 50 years of age, had been married to this his second wife nineteen or twenty years, and had children by her. For some years previous he had been subject to fits of intoxication. These, of late, were followed by delirium tremens, which generally lasted several days. In these paroxysms, he entertained great fears for his safety—ran about the village as if attempting to escape pursuit. At another time he con-

cealed himself between a straw bed and a feather bed in his own house. He would point his gun from a window, as if for defense against imaginary persons. He was also very watchful.

"The prevailing maniacal delusion was that his wife was in combination with his neighbors, and his son by his first wife, against his life. He had charged her, during his paroxysms, with criminal intimacy with these, and had threatened to kill her on Sunday. He was intoxicated Monday, Tuesday and Wednesday. On Wednesday evening, he complained of being unwell, but seemed to be rational. He slept none that night, and next day the family thought him crazy, but were not alarmed. In the course of the day he took an ax and went to a neighbor, whom he desired to return with him, as he stated they wanted to kill him (monomania of persecution). He spent the remainder of the day at home, apparently in terror and agitation, manifested jealousy of his wife, barred the doors, and fancied that the person of whom he was jealous was manufacturing ropes up stairs to hang him. In the course of the afternoon he suddenly committed murder. His wife was sitting by the fire, and he walked into the room. After the fatal blow on the neck, he followed it by two or three on the face. His eldest daughter seized the ax, which he yielded, but took a scythe and attempted to strike her. She defended herself until the door was opened. When arrested, he acknowledged the homicide, and knew, he said, that he would be hung, and regretted that he had not done it sooner. After being committed, he became regular, and expressed sorrow for what he had done. On trial, three medical witnesses agreed that he labored under *mania à potu* when he committed the homicide.

"For the defense it was urged, that when *drunkenness gives rise to insanity*, it should cause *immunity*, and hence form a legal excuse. On the other hand, the counsel for the people remarked 'that Birdsall knew that his delirium followed his intoxication, and hence it was voluntary. The law therefore held him accountable for actions during such a state.' The verdict was murder in the first degree, and he was sentenced to death." It is needless to add that there was not the slightest foundation for the insane vagaries of Birdsall, and no "reasonable motive" for his act.

Let me cite still another case, reported as a newspaper item. "Alexander C. Wingate, a wealthy resident of Woodford Co., Ky., was shot dead at about 4 o'clock this morning (March 29, 1882), on an Ohio and Mississippi train, near Mitchell, Ind., by a man named Haynes, who was crazed by drink, and had no provocation for the shooting.

"Mr. Wingate was returning home from a business trip from the West, and was in a sleep-

ing-car. Haynes entered the car, laboring under great excitement, and said to the porter and several passengers that he had been followed by thieves from San Francisco, who were bent on robbing him (mania of suspicion). He begged the passengers to keep his money—which amounted to only \$90. The porter tried to pacify him, but he grew more desperate, and flourished his revolver around wildly. The train men were either too cowardly, or did not have sense enough, to wrest the revolver from him, and eject him from the train.

"At this time, Mr. Wingate stepped from his berth. Haynes immediately confronted him with the revolver, and exclaimed, 'Give me my money,' and fired. Wingate threw up both hands, cried 'I am shot,' and sank down dead. The maniac (from alcohol) turned, and fired two random shots, then darted past the passengers and out of the car door, and jumped off the train, which was running at the rate of 45 miles an hour. He landed safely, walked half a mile to a creek, stripped himself naked and jumped into the stream. His dead body was found there this morning. His clothes were found hanging to a tree 100 yards distant, and they contained \$90 in gold, a gold watch, an express receipt for \$400 sent from El Paso, Tex., to New Salem, O., and a quart bottle of brandy, half full. In his valise was found a gambler's 'lay-out.' Haynes is from Yuma, Ariz. He was evidently laboring from delirium tremens (?) at the time of the deed, or rather '*mania à potu*.'"

Although homicide was the prominent feature of the case, "homicidal mania" was not. Haynes did not kill Wingate because a predisposition to kill some one predominated, but as an act of supposed self defense, and to resent the injustice that he supposed Wingate had inflicted on him. In other words, the "mania of persecution" was the leading form of insanity—a form very common in cases of insanity arising from alcohol.

There is no crime in the calendar that these alcoholic maniacs may not commit. Their reason is temporarily dethroned, they are unconscious of not only the character of the act, but of the acts themselves, and are therefore irresponsible. The following case shows the complete annihilation of all mental and moral responsibility.

"A young man in Madison Co., in this State, in the year 1859, was attacked with alcoholic delirium for the third time. While under the attack, he killed his father and mother, cut out their hearts, which he roasted and ate. He was arrested, thrown into prison and indicted for murder. He was brought into court for trial, when Judge Gray, of the Supreme Court, stated that the case could not be tried, '*as there was no motive to prompt a man to commit such a crime*.' This man was sent to an insane asylum."

Let me cite a case taken from the records of

Broome County Circuit Court: "On Decoration Day, 1885, George Axtell, a young farmer of the town of Middletown, New York, visited Deposit village, and became intoxicated. While in this condition, and without provocation, he ran amuck (a mok) with a pistol and killed three men. Axtell was condemned to be hanged, but died in jail of heart disease, prior to the date fixed for his execution, or we would have had to record another case of judicial murder."

Axtell was undoubtedly affected by "*mania à potu*," or "alcoholic frenzy" or mania, when he committed the homicides, and was entirely irresponsible. These cases of "alcoholic homicidal mania" are not uncommon, and the daily prints often furnish us with similar examples.

I might cite many cases in point showing the various kinds of alcoholic insanity, and the crimes committed, as well as the judicial opinions expressed, but let these suffice.

The question whether "premeditation" could be proven in the case of the criminal inebriate could not, we think, weaken the position taken of the irresponsibility of the inebriate. In some instances apparent premeditation may exist; but the absence of a "reasonable motive" should certainly give force to the plea of irresponsibility.

The popular impression seems to be, testifies Mr. John C. Salter, the warden of the State penitentiary at Chester, Illinois, that a criminal is necessarily a drunkard.

The large proportion of criminals, such as burglars, forgers and counterfeiters, need clear brains, steady nerves, quick perceptions, to carry out their plans, which would be impossible under the influence of intoxicating drink.

The assassin may drink to nerve himself to the deed, but only to that extent, and no more. This form of crime, where the alcoholic stimulant is taken *deliberately*, with the intention of nerving the criminal to the act, is most aptly shown in the great Shakespearean tragedy. Lady Macbeth, so stimulated and nerved as an accomplice to Macbeth in his bloody deed, thus soliloquizes:

That which hath made them drunk hath made me bold;
What hath quenched them hath given me fever.

Here the antecedents, the motive and the subsequent events of the plot take precedence, and the alcohol taken within to produce drunkenness—not lethargy—plays but a secondary and inferior part in the whole tragedy. The "deep damnation of the taking off of Duncan" is not lessened one whit by the fact that alcohol was used by the conspirators and murderers to nerve themselves for the tragedy. The alcohol did not prompt the deed; it was deliberately taken to enable them to perform it—a condition quite the reverse of the insane inebriate or the person suffering from "chronic alcoholic mania," in which the "mania of suspicion," or an acute alcoholic

mania is developed. Here the maniac, in his sudden fury, cyclonic in its violence and rapidity, kills those nearest to him without premeditation or motive.

To sum up the logical conclusions resulting from the study of criminal inebriates in a single paragraph, we would state:

"An act, to be criminal, and to be enrolled under the code as a crime, must show such pre-conception, or preparation, or motive, as to make it an act of deliberation, and the intent must be proven by the relation of the accused party to the deed, before, during and after its commission.

"If from simple impulse, without premeditation, the act must be shown to have been uninfluenced by any drug capable of affecting the intellect and developing maniacal impulses; and further, that the person committing the act was in full possession of his mental faculties, and was uninfluenced except by a reasonable motive that prompted the deed. In special cases, as in murder, the ground of self-defense may satisfactorily be excluded. Under these circumstances, the person has committed a crime, and the evidence must acquit or condemn him."

In all cases, a history of previous *confirmed inebriety*, coupled with an entire absence of *reasonable motive* or antecedents, should give the person committing the act the full benefit of the plea of irresponsibility, and the same "legal excuse" that is applied to the acts of "insane criminals."

And in conclusion, I have only to add that the "criminal inebriate" should be dealt with in the same manner as the "criminal insane."

HOW MUCH OUGHT A SMALL CITY TO PAY ITS HEALTH OFFICER?

BY HENRY B. BAKER, M.D.,

SECRETARY OF THE STATE BOARD OF HEALTH, LANSING, MICHIGAN.

[From advance sheets of "Proceedings of a Sanitary Convention held at Negaunee, Michigan," August, 1891.]

I presume that the reason why each city is required by law to have a health officer, is that sentiments of common humanity dictate that proper effort shall be made, constantly, by the officers of every locality, for the best possible protection of human life and health within their jurisdiction.

But in this paper I propose to go a step further, and to point out the fact that this high humanitarian position which the law contemplates, when it requires cities to guard the health of their inhabitants, and to contribute facts and statistics for the general welfare of the people of the State, that all this from a financial stand-point, pays the people of each city and of each locality. I propose to speak especially of the city of Negaunee, but the same principle which applies to Ne-

gaunee is applicable to other cities and localities.

Let us estimate the population of Negaunee as about six thousand, and that the death rate in Negaunee is about the same as it has been in other parts of Michigan where it was not specially influenced, say about seventeen per thousand inhabitants per year. Then, the average number of deaths in Negaunee per year would be about one hundred and two. Of this number, a little less than twelve per cent. would be from consumption, six and a half per cent. from diphtheria, two and seven-tenths per cent. from scarlet fever, three and two-tenths from typhoid fever. These are all communicable diseases, and they are preventable through measures which are now known to health authorities.

Reliable statistics, collected by the Michigan State Board of Health, have proved that (even after the disease is introduced) about seventy-five or eighty per cent. of the deaths from diphtheria and from scarlet fever are prevented if complete isolation of all infected persons is enforced, and there is then thorough disinfection of all infected substances.

I believe that there is a similar saving of lives from loss by typhoid fever, where the proper local health measures are enforced. Relative to typhoid fever, these measures are not so completely dependent upon efficient services by a health officer as are those relative to diphtheria and scarlet fever, yet they will not be likely to be effective except such services are maintained.

It is possible then, through and in connection with the services of an efficient health officer, to save, in a city the size of Negaunee, in each year, the lives of about five persons from death by diphtheria, about two persons from death by scarlet fever, and, I think, about two persons from death by typhoid fever. In some years they might be more, and in some years, less; but these are the average figures per year, for a series of years. Surely the saving of these lives, and of the sickness of the still larger number of persons, is well worthy the effort of the city in compliance with State laws. But I wish to point out the fact that in saving those lives, and in the lessening of sickness, there is saved to the city that which has cost money, and that which if lost, would have been a loss in money values far in excess of the cost of any effort which the city puts forth in sustaining an efficient health service. It costs money to raise up children to the age when they become producers of wealth. If children are permitted to die of communicable and preventable diseases, there is a great waste not only in life, health and happiness, but also in money. Statisticians have computed the average value of an adult person, for what that person will earn in excess of cost of maintenance, as about one thousand dollars. Practically about the same conclusion was reached by those in the

south, who some years ago bought and sold slaves, a good one selling for about eight hundred dollars.

If, now, we consider that the seven persons in Negaunee in each average year, whose lives should be saved from diphtheria and scarlet fever, are each worth five hundred dollars, there is in each year a saving of three thousand five hundred dollars from those two diseases alone. If two lives are saved from typhoid fever by disinfection of infected matters, and by other methods which a good health officer could teach, the persons saved from that disease would ordinarily be in the prime of life, and this saving should be counted as two thousand dollars.

There is, then, a probable saving of \$5,500 a year in Negaunee, by such work as can be and should be done by and in connection with the services of an efficient health officer, and this with reference to only three of the dangerous communicable diseases. Of course, I believe that lives can be saved from other diseases than those in which I have just computed the saving, but I have omitted most of them because not needed in my argument, and I have selected the three which I mentioned, because in diphtheria and scarlet fever we have the absolute proof that lives can be saved by measures that are well known to us, and in typhoid fever it has been proved beyond question that the disease can be almost entirely prevented by other measures which are equally well known.

In this brief statement of facts I have omitted all consideration of the costs incident to sickness, including physicians' compensation, medicines, nurses, loss of time, etc., also the cost for funerals, and have confined myself rigidly to the money losses through the actual deaths from three diseases. Without the efforts which I have supposed to be put forth by an efficient local health service, there is a money loss in a city the size of Negaunee, through the actual deaths from those three diseases, equal to \$5,500 per year. Is it not better and really more economical to pay \$5,500 per year for public health service than to bury that which is equal to that amount in money value in the graveyard?

I am ready to admit that this counting of the cost of the life blood of your neighbor and perhaps of yourself; of your neighbor's child, perhaps of your own child, is to me exceedingly repugnant; but so long as your neighbor's life and your own, the lives of your neighbor's children and of your own, are not properly guarded, but are permitted to be endangered from these same diseases that I have mentioned, it is plain that some other argument than the usual one must be presented.

Undoubtedly, public-health work in cities is neglected because of lack of information as to *how much* effort should properly be expended.

Such computations as those I have put before you should help us to arrive at conclusions on this point.

We will admit, if you please, that when deaths occur, the loss is not equally distributed among the people of the city; generally the loss falls most heavily upon the bereaved family, and this is especially true if the death is of the breadwinner of the family. But it should not require much argument to show that the prosperity of a city depends greatly upon its healthfulness and the safety of life therein, and that, in a long series of years, the deaths are distributed somewhat equally among the people, and that, even if they are not equally distributed, a high moral sentiment should prompt us to guard the common safety of life among us. It was recognized, even before the Declaration of Independence, that to each citizen the right to exist, the life of the individual is among the inalienable rights to secure which "governments are instituted among men." It is plain, therefore, that one of the highest, perhaps the very highest, function of government is to guard the lives of the people.

Having reference, then, to only three important diseases, it seems plain that a city the size of Negaunee has the undoubted right to expend in every year at least \$5,500 for the restriction and prevention of diphtheria, scarlet fever and typhoid fever. I think that there is good reason to believe that the citizens of Negaunee would make money by this work; because they would incidentally save lives and cases of sickness from other diseases than those I have mentioned; and, besides, in my account of the losses by those three diseases, I accounted only for the losses by reason of the deaths, leaving out of the account all the great expenses for the sickness. For instance, from the two diseases, diphtheria and scarlet fever alone, an efficient health service, properly supported, should in each year save all the expenses incident to forty-three cases of dangerous sickness.¹ All such saving would be a clear profit, in case the city expend the \$5,500 per year, as previously suggested, and save \$5,500 worth of lives, as I have shown may reasonably be expected.

I would advise that at least \$1,000 a year should be expended toward securing a water-supply which is above suspicion. This with special reference to the prevention of typhoid fever. I would use another \$1,000 per year toward securing good sewerage, and a proper disposal of waste. Five hundred dollars would

¹ The reports, compiled by the Michigan State Board of Health, show that for each death from scarlet fever there are over ten cases of sickness from that disease; that for each death from diphtheria there are four cases of sickness from diphtheria. Therefore, the seven deaths on an average yearly from diphtheria in the average place the size of Negaunee should represent twenty-eight cases of sickness, and the three deaths from scarlet fever represent thirty cases of scarlet fever—fifty-eight cases from the two diseases; and, inasmuch as 75 per cent. of them should be prevented by an efficient health service, forty-three of the cases should not occur.

pay for disinfectants, for printing annual and other reports of sanitary officials, including the water and sewerage commissioners, and for other incidental expenses. This would leave \$2,000 per year with which to pay the salary and expenditures of the health officer.

The law now requires much more of the health officer than it formerly did; and it provides fines and imprisonment for neglect of duties connected with dangerous diseases. If the health officer attends to such diseases, he must lose his ordinary practice. Accordingly, his compensation should be greater than formerly; it should be greater than he could obtain for the same time by the regular practice of his profession as a physician. The life and health interests of the whole people of a city are of more consequence than those of the patrons of any single physician, no matter how large and lucrative his practice may be. But there is another still more important consideration. No reputable physician claims to *cure* any real specific disease such as diphtheria, scarlet fever or typhoid fever. After a person has contracted the disease, it is important to have a skilful physician to watch and guard the patient as thoroughly as possible through the course of the disease, but no physician claims to stop or break up the course of the disease. Physicians are needed to lessen the chances of death among those who have been permitted to contract these preventable diseases. The truest economy consists in lessening the chances of contracting such diseases. The compensation to physicians should be for the prevention of all such diseases, then it would not be required for the cure, during which a large percentage of the cases prove fatal, and this under the best methods of cure in the hands of the most skilful physicians. About the only practicable method of transferring the compensation to the proper kind of service, is to employ the physicians as health officers and as members of local boards of health.

In many places the people are so ignorant on these subjects, that they do not provide sufficient compensation to induce the best physician in the city to act as health officer, and to give his whole time to the public service. It is noticeable that it is in just those cities which do not sustain an efficient board of health, and do not constantly employ and pay for the services of a first-class health officer, that the dangerous diseases are so destructive. I am informed that here in Negaunee, the health officer receives from the city only \$500 per year. That is for guarding the interests of the health and life of all the 6,000 people in the city. At the same time there are in Negaunee six or more physicians, who are paid and well supported, each attending to the sick among only a portion of the people of the city.

I fear that the saving of life and treasure which I have computed as possible has not all been

made in Negaunee, but I look forward to a time when, through the payment of a few thousand dollars per year for a complete and efficient health service, there will be saved the lives of even more than the nine persons whom I have computed should be saved from diphtheria, scarlet fever and typhoid fever, and to a time when Negaunee shall have become one of the favorite summer health resorts of those who every summer seek to avoid the heated atmosphere of localities farther south.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopædic Surgery.

Stated Meeting, October 16, 1891.

SAMUEL KETCH, M.D., CHAIRMAN.

Dr. Royal Whitman presented a patient illustrating the application of a brace for the more perfect fixation of the spine in disease of the middle dorsal region. The appliance consisted of two saucer shaped pads covering the prominence of the shoulders, connected by an unyielding steel bar, passing across the chest; and two triangular hard rubber pads covering the lower two-thirds of the scapulæ, connected by a steel bar. The Taylor back-brace was applied as usual, and the back bar attached to its upper portion. The shoulders were then pressed back to their full limit, the front pads placed in position, and firmly attached to the brace by straps passing above to the neck bar, and through the axillæ to the back pads which held the scapulæ against the thoracic wall. Motion of the spine was thus confined entirely to the neck. Although the necessary movements of the arms were not restricted, forward reaching movements, which were always accompanied by flexion of the dorsal spine, were entirely prevented. This principle, the restraint of certain movements of the arms which tended to increase the existing deformity, was the point to which he wished to call the attention of the Society, as he was not aware that its importance had before been insisted on.

Dr. R. H. Sayre fully agreed with Dr. Whitman as to the necessity of keeping the shoulders back in this class of cases, but the difficulty hitherto had been to maintain such apparatus in proper position. In a paper which he had read at the recent meeting in Washington, he had called attention to the fact that when the disease was situated high up in the dorsal region, the plaster of Paris jacket did not give proper support, because it failed to hold the shoulders back, and that in such cases, he was in the habit of employing pressure backward on the tips of the shoulders.

Dr. Newton Shaffer thought that the apparatus exhibited acted admirably in fixing the shoulders, but it was open to the grave objection that by exerting pressure on the scapular plates in this way, the uprights are prevented from exerting the proper amount of pressure at the seat of the disease, and so the apparatus was not able to arrest the traumatism of respiration. He thought this was a defect inherent in the apparatus, and not, as Dr. Whitman believed, simply an accident, due to improper fitting of the brace to the patient's spine.

Dr. Whitman replied that he thought the apparatus exerted all the pressure that the skin would bear, and that by slightly modifying the curve of the uprights, the defect noticed by Dr. Shaffer would disappear. His object in presenting the apparatus was to elicit a discussion on the question, whether or not it was desirable in this particular class of cases, to attempt to control the forward movement of the shoulders.

BOND'S OPERATION FOR TALIPES VALGUS.

Dr. A. M. Phelps presented a young man whom he had been treating for a number of years for a very severe case of talipes valgus. Almost all methods had failed to give more than temporary relief, although in one instance there was no relapse in the case for a whole year. The patient constantly wore a support for the arches during the time.

The patient sought for relief not so much on account of the deformity, as because of the severe pain which he suffered, and which prevented him from standing on his feet; without shoes, he could hardly walk. His occupation was printing.

In conversation with Dr. Bond, of Westminster Hospital, London, Eng., Dr. Phelps had learned of the operation, which in its author's hands had been successful.

The operation performed by Dr. Bond was for the purpose of relieving the pain, which it certainly does. He alluded to the operation as "firing," the same as is done for the relief of spavin in a horse.

The operation consists in making transverse incisions with a Paquelin cautery, beginning at the inner malleolus, and extending one-third of the distance across the sole of the foot, cutting through the cellular tissue down to the muscles. About four of these incisions suffice. Two semi-circular incisions are made, crossing the transverse ones. It seemed to Dr. Phelps that if the arch of the foot, before the operation is performed, were well shoved up in place, and held with plaster of Paris for a few weeks, that the shortening of the tissues in the sole of the foot by cicatricial contraction, would be more effectual, and would hold the arch in the normal position.

The operation when applied in this manner

for the purpose of shortening the girders of the arch of the foot, is identical in principle with an operation which Dr. Phelps performed and reported to the American Orthopedic Association in 1889.

One objection which has been urged against the open incision method for talipes equinus, is that the scar is quite likely to be sensitive, and it is interesting to note that in this case, the amount of the scarring being considerable, the patient walks upon the scarred tissues without any pain, and is able to work at his trade. The only support to the foot needed, is an ordinary shoe slightly thickened on the inner side.

Dr. R. H. Sayre said that the amount of pain experienced in these cases of flat foot bears no relation to the amount of deformity. This patient's foot is still turned outward, and as in many other cases, when the foot is brought into the normal position, there is a very noticeable involuntary twitching of the peroneal muscles. The patient had been made comfortable once before for a period of a year, so that it was entirely too soon to say that the case would not relapse. As the arch of the foot is in large part maintained by the deeper structures, it seemed doubtful whether the scar tissue, which did not go beneath the muscles, would be sufficient to hold up the arch, although at present it did this very well.

Dr. A. B. Judson said that in view of the well known fact that cicatrices after burns contract persistently and with great force, the operation was not only ingenious but quite likely to prove successful.

Dr. Whitman thought the operation absurd and extremely unscientific. No case of flat foot is cured until the important movement of abduction is perfectly free to its utmost limit. In the present instance, abduction is not possible, and the case is only relieved, not cured. The only way to cure flat foot is by increasing the power of the muscles which support the weak portion of the foot.

Dr. Halstead Myers said that as the pain in flat foot is largely due to periostitis about the attachments of the ligaments involved, and in the joint structures themselves, this operation with the Paquelin cautery might act beneficially by counter-irritation, just as it does in many cases of joint disease elsewhere. Relief from pressure during the healing of the wound, was also an important factor in the cure.

The President stated that if this procedure of Mr. Bond gave permanent relief from pain, that it would constitute a valuable accessory to our methods of relieving this troublesome symptom. In working people, in whom this deformity occurred most frequently, the question of a perfectly formed or perfectly acting foot was secondary. What patients wanted was first, relief from

pain, and secondly, feet that would give them an opportunity to earn a livelihood.

Dr. Phelps, in closing, said that the case was not presented as a cure for the deformity of hallux valgus, but that the flat feet seemed to be cured.

He had never observed periostitis in cases of flat foot, but he had frequently seen inflamed medio-tarsal joints, the result of pressure, and even the growth of new bone about the joints precisely as is seen in severe forms of lateral curvature.

The scaphoid bone is really the key-stone of the arch, and when it is dislocated downward by the lengthening of the tissues in the sole of the foot, it causes great pressure. The patient will experience pain. This pressure long continued, results in inflammation and growth of bone about the joint.

He thought it more scientific to shorten the girders of the sole of the foot than to do an osteotomy.

A CASE OF MULTIPLE JOINT DISEASE.

Dr. R. H. Sayre presented a little boy who had had a strange combination of diseased joints, without any rheumatic history.

When about two years old, the boy had a severe attack of scarlet fever, which was followed by an ischio-rectal abscess and a double otitis media, which still continues. About ten months after the attack of scarlet fever he fell, and shortly afterward the left knee became swollen and tender. A splint was applied, and the knee soon appeared well. Shortly after this, the right knee and the right hip-joint became successively inflamed. He was then treated for about a year by traction, first in bed and afterwards with a long traction hip splint. After this, the left knee, the right knee, and the left shoulder became successively inflamed, and so severe was the inflammation in the shoulder, that at one time it was almost completely ankylosed. In 1888, after an injury, the right knee and right hip became swollen and tender, and it was at this time, that the case first came under his observation. After the flexion had been overcome, a splint was applied, which produced traction on both the knee and hip-joint. Photographs were exhibited, showing the case with the splint applied. Last July it was considered safe to remove the splint. At present he has no pain; extension is good, and flexion can be made to a right angle. There is almost perfect motion at the hip-joint. He had looked upon the joint lesions as probably tubercular, but it was possible they were metastatic.

Dr. H. L. Taylor did not believe the joint lesions were tubercular.

The President also thought the whole clinical history pointed away from tubercular disease,

and that the scarlet fever had probably given rise to a rheumatoid condition.

Dr. A. M. Phelps said the trouble was either rheumatic or metastatic, and as the joints did not suppurate, the former was the more probable origin. While the application of the splint probably assisted in bringing the case to so favorable a termination, it was quite likely that constitutional treatment alone would have been sufficient. He had been misquoted with reference to the occurrence of flexion at the hip-joint. Where the *whole* number of cases have been reported, he believed the statistics would show that not five per cent. have recovered without angular deformity; yet he believed that not one single case of hip-joint disease need recover with angular deformity.

Dr. Sayre said that it was not material to this discussion whether the joints were tubercular or septic. The point he desired to bring out was that, no matter what the nature of a long-continued inflammation of a joint, protection of that joint is necessary. He agreed with Dr. Phelps that no case of hip joint disease ought to have angular deformity.

AN UNUSUALLY SEVERE CASE OF CONGENITAL LATERAL CURVATURE.

Dr. R. H. Sayre presented such a case. The patient is now fourteen years of age, but her mother says that at birth the deformity was nearly as great as now. It was one of the most severe congenital cases he had ever seen, and she first came to him one week ago. Examination at that time showed that between the lower and upper ribs was a large V-shaped gap, through which the liver could be felt. At the age of six years, she had pneumonia, and shortly after this, an abscess, which was probably connected with the pleura, opened through the right thoracic wall. Her breathing is puerile; there is no cardiac lesion. At the time of her birth, the child presented transversely, and the labor was difficult, so that it is possible that this may have had something to do with the deformity. He thought all the ribs were present. When first seen, her height was four feet six and three quarters inches, but after being suspended, there was a gain of five-eighths of an inch. He desired to call particular attention to this increase in the height as the result of the suspension. In another case, between September 5 and October 15, there has been a gain of three-fourths of an inch; in another, there was also a gain during a month of treatment of three-fourths of an inch, and in still another, which measured before treatment four feet nine and seven-eighths inches, the measurement after about a month was five feet one and one eighth inches.

Dr. H. W. Berg said that the mere fact that the patient had such excellent use of her limbs

would show that the curvature was not due to a lesion of the brain or spinal cord. If the ribs were congenitally absent, there would be sufficient cause for the curvature without supposing any injury during labor.

Dr. Judson remarked that the case was an illustration of the fact that in lateral curvature the kyphosis is sometimes very considerable, and may be as serious as in Pott's disease.

The President said that some years ago he had called attention to the frequency of lateral curvature in very young children, most of which he believed to be of congenital origin. He had repeatedly urged the necessity of the careful examination of infants' spines, as a matter of routine, and thus, were deformity present, an early opportunity for treatment. He believed that were this done, we should not see such distressing deformity as Dr. Sayre had presented. Quite recently, Dr. F. Beely, of Berlin, had pointed out that in these early cases of scoliosis, the bones of the head were not symmetrical. The case just presented was instructive as showing how great may be the deformity in cases which have not had the benefit of early and judicious treatment. Notwithstanding the deformity develops very slowly, so many cases apply for treatment with the deformity well marked that he was inclined to believe that a large proportion of all cases of scoliosis in children are congenital.

Dr. V. P. Gibney presented a case of hip disease showing

A REMARKABLE RECOVERY BY NATURE'S METHODS.

A boy of eight years was admitted to the hospital in 1882 with disease of right hip in second stage. Family history tuberculous. Disease dated back to the previous April. On admission he was fairly nourished, hip flexed to 100° , and held in this position. *Practical* shortening of three and three quarters inches. On July 7, 1883, flexion had increased to 135° , and an abscess filled the whole gluteal region. On October 12 the abscess opened. November 16 he had become greatly emaciated, pale and waxy, the thigh acutely flexed on the abdomen and abducted, the head being apparently dislocated on the dorsum, while the whole thigh, from the junction of the lower and middle thirds to the trochanter major, was undermined, and large quantities of pus were discharging from two sinuses. Could only sleep with the aid of two drachms of the U. S. solution of morphia, and his condition was so bad that it was thought there was no chance of his recovery, and he was advised to be taken home. On the 27th of November he was visited by a member of the house staff, who found him suffering from diarrhoea and night sweats, with poor appetite, a pulse of

130 and a temperature of 101° . On the 7th of December his condition was about the same, except that a bed-sore, as large as a half dollar, had formed over the trochanter on the sound side. Not seen again until October 14 of the present year, when he returned, looking hale and hearty. He said that after leaving the hospital, he had been confined to bed for one year and a half, and had then begun to go about on crutches. For the past four years he had been wearing a five-inch high shoe. The site of the old abscesses and of the bed sores are marked by very large cicatrices; the angle of greatest extension is 100° , and that of greatest flexion, 90° ; the adductors are very tense. His measurements are as follows: R. A., $27\frac{1}{2}$; R. U., 30; R. T., 6 in. down, $13\frac{1}{2}$; R. K., 12; R. C., $10\frac{1}{4}$; L. A., 29; L. U., 36; L. T., 6 in. down, $17\frac{1}{4}$; L. K., 13; L. C., $11\frac{3}{4}$.

THE NECESSITY FOR EARLY MECHANICAL TREATMENT IN INFANTILE PARALYSIS.

Dr. W. R. Townsend read a paper with this title, calling attention to the various stages of the disease, the methods of making a prognosis as to return of power and as to deformities resulting, and demonstrating the value of mechanical treatment in all stages, but especially in that before the appearance of deformity as a method of prevention.

Dr. H. W. Berg called attention to the importance of avoiding heavy apparatus, which often seriously interferes with the paralyzed muscles. In addition to this, all such apparatus should be applied from a *healthy* fixed point of support. One of the most troublesome symptoms in long-standing cases of infantile paralysis is the low surface temperature. He had given relief in two recent cases by wrapping the limbs at night in cloths wrung out of ice-water, and covering these with warm bedclothes.

Dr. Whitman said that the author spoke of equinus and equino varus as the most common deformities in untreated cases. Equino valgus he thought to be the most common deformity in treated cases, and it was very difficult to prevent.

Dr. Shaffer said that in the fourth stage, where contractures occur, and paralyzes are very pronounced, he had met with a very surprising series of cases. He had records of four cases of equinus in adolescents and adults, where the anterior tibial muscles and the quadriceps extensor femoris were involved, and the patient sought relief on account of the deformity of the feet. He had, by means of his antero posterior traction shoe, restored considerable power to these muscles. Another important point was the improvement in the nutrition of the feet resulting from this traction. One patient used to come periodically, as she expressed it, to "get her feet warm." Not only would the feet get warm

during the application of the traction, but they would remain so for the rest of the day. He had never seen such results follow the use of electricity and massage, and similar methods of treatment, with or without tenotomy. Of course, in calcaneus cases, this traction cannot be applied, and hence these desirable results cannot be obtained. The cause of the improvement seemed to be the peripheral nerve irritation occasioned by the traction, exerted principally upon the gastrocnemius and all the other resisting tissues. He had known the calf circumference to increase half an inch by actual measurement, during a month of this treatment.

Dr. R. H. Sayre thought that one explanation of the increased power of the quadriceps extensor could be found in the fact that the feet were placed in a position where they can be used more advantageously.

Dr. Judson considered the paper worthy of much attention, and it was a matter of congratulation that the profession at large already recognized the importance of sending these cases to orthopaedic surgeons.

Dr. H. L. Taylor thought that we might go even further than the author, and state that a very large majority of the deformities of the lower extremities are preventable by proper orthopaedic treatment. A very badly deformed foot from slight paralysis will often prevent the use of many muscles, and even where muscular power cannot be restored, proper mechanical treatment will often secure to the patient very respectable locomotion. Mechanical treatment, by enabling the patient to go around more naturally, will often increase the warmth of the limbs, but for very bad cases, he had for a long time made use of hot, dry air, or of two woollen stockings, one underneath, and the other over the brace, to keep up the proper temperature of the parts.

The President said that it was a popular idea that braces tend to bring on increased weakness of limbs, and various disorders, and until recently, the great obstacle to beginning mechanical treatment in the early stages, has been the opposition of parents and of the attending physician. Within the last year, he had seen two or three cases quite early, and had noticed a stage of tenderness, which might possibly prove a temporary contraindication to mechanical treatment. He did not think this condition had been mentioned very generally by orthopaedic writers.

Dr. Whitman said that he had many times met with this condition.

Dr. Townsend, in closing the discussion, said that he thought much of the opposition to braces arose from the fact that orthopaedic surgeons were not agreed among themselves as to what kind of apparatus was most suitable for the treatment of the different classes of cases. He desired to em-

phasize the importance of that part of the paper which refers to the experiments of Mr. Young on electrical examinations of muscles. If, by such an examination, one could ascertain that, in a given case, contractures and deformity would result, the task of persuading parents to allow their children to receive early orthopaedic treatment would be a much easier one than now.

Medico-Legal Society of Chicago.

CHEMICAL CONSIDERATION IN POISONING.

Presented before the Medico-Legal Society of Chicago, Oct. 3, 1891.

By C. D. WESCOTT, M.D.

(Concluded from page 774.)

Arsenic is still an ingredient in the coloring matter of a great many articles which children constantly handle; it is used in the coloring of decorative paper and cardboard, in the coloring of children's toys, in crayons, in the coloring of candles which are used on Christmas trees; it is found in many patent medicines, in rat and mice poisons, all of which are left lying about in the most careless way, and it is truly wonderful that there are not more cases of poisoning.

Another point I would speak of, is in regard to the organs which should be selected from a dead body supposed to have died from arsenical poisoning to be sent to the chemist. Different investigators have not agreed as to which organs contain the greatest amount of arsenic, but it is well established that the stomach and its contents, a portion of the liver, the kidneys and a portion of the brain and spinal cord should be submitted in all cases where possible. A portion of the brain should always be obtained, as it contains the largest percentage of arsenic in many cases, though it is said by some investigators that the spinal cord contains the greatest relative quantity.

In regard to the antidote, I believe we should all have an old disused bag in which we could constantly keep a stomach tube, some of the more important antidotes and restoratives, that we could pick up and run with in an emergency. The most convenient substance from which the antidote for arsenic can be prepared is a solution of ferric chloride, two ounces to an ounce of ordinary sodium carbonate or washing soda; the latter can be quickly dissolved in warm water, and the solution of ferric chloride can be added, and we have a mixture which we need not strain or fuss with, but which can be given to the patient at once.

I have little to say in the way of discussion of the papers that have been read. Dr. Nelson referred to Fowler's solution as an antidote for snake poisoning. I think if I were bitten I should prefer to trust to the common antidote, whisky. Dr. Nelson suggested that the coma in arsenic

poisoning might be due to nremia. It occurred to me while he was speaking that possibly it was due to a direct action of the poison upon the brain substance, inasmuch as such relatively large quantities of arsenic are found in the brain post-mortem.

Dr. Moyer's case of Paris green poisoning is a puzzler, but it is no doubt a fact that Paris green is sparingly soluble, and is also a fact that stomachs and intestines differ very much as to their absorptive power and they differ very much as to their sensitiveness, and we would have to consider these facts in making up our minds in regard to this case. While death has been caused by the ingestion of one grain or less, of arsenious oxide, two ounces have been taken into the stomach, and recovery followed.

THE PATHOLOGICAL ANATOMY OF ACUTE ARSENICAL POISONING.

Read before the Chicago Medico-Legal Society, Oct. 3, 1891.

By DR. LUDWIG HEKTOEN, of Chicago.

In this communication only those anatomical changes that may be caused by acute arsenical intoxication, and are susceptible of demonstration in the fresh cadaver, will be considered.

While the frequency of poisoning with arsenic is steadily diminishing in certain European cities and countries, this mode of terminating life appears to be quite popular in this city. Of 431 cases of fatal poisoning investigated at the Medico-Legal Institute, Berlin, during the years 1876, 1877 and 1878, only eight were instances of arsenical intoxication; of 120 cases of suicide examined in Vienna during 1874 and 1875 only two had selected arsenic. In France, in 1857, arsenic was the poison employed in 35 out of 63 murders by poisoning; in 1860 it was used only 3 times in 32; in 1862, 5 times in 38.¹ Of 47 cases of acute poisoning admitted into the Cook County Hospital,² in Chicago, 1890, 8 were instances of arsenical poisoning. In 59 cases of poisoning investigated by the coroner of Cook County³ during the year 1890, 32 were due to arsenic; of the 59 cases 54 were suicides; 5 murders all due to arsenic; two of the murders to the mixture known as "rough on rats," 2 to arsenic in solution, 1 to Paris green. In 23 out of the 27 suicidal poisonings with arsenic "rough on rats" was used. One, and perhaps the principal reason, for this astounding frequency of arsenical poisoning here is undoubtedly the ease with which the poison is obtainable. Any child can be sent to a drug or grocery store for unlimited quantities of arsenic in the mixture called "rough on rats."

What destructive action arsenic in this form

may produce upon the red corpuscles, and the occurrence of thrombosis in the capillaries and larger vessels would certainly explain the hæmorrhages, some of the areas of necrosis and degeneration, as well as many of the clinical symptoms observed in cases of arsenical poisoning. This phase of arsenical poisoning will undoubtedly be subjected to future and fruitful investigation. It at once suggests itself that the microscopic demonstration of capillary thrombosis in a suitable case of supposed arsenical poisoning would go far to settle the question of ante- or post-mortem introduction of the poison in case doubt should arise on this point.

In order to bring before you the anatomical changes of acute arsenic poisoning I shall take the liberty to briefly describe the post-mortem appearances in two or three instances.

Case 1. Poisoning with "Rough on Rats."—This occurred in a family of four and was due to the sprinkling of "rough on rats" upon the corn eaten at the fatal supper. The father died about twelve hours after the poisoning, the mother, eighteen; in both the clinical symptoms were quite classical.

The post-mortem examination was made twenty-four hours after death. The appearances were quite similar in both, hence only one description is necessary at this time. The external appearances were absolutely negative except that the man's skin was yellowish; the facial expression was not indicative of any special emotion. The peritoneal cavity was empty, the peritoneum normal; the stomach was dilated in both instances, hanging low down; the subserous veins were moderately filled with blood; in each case the stomach contained about twenty-four ounces of turbid watery fluid of negative odor; the mucous membrane was rather pale, opaque and somewhat swollen, but in the cardiac and pyloric regions were punctiform and linear hæmorrhages and extensive areas of capillary hyperæmia. The commencement of the duodenum was quite uniformly red, the mucous membrane swollen; in the entire small intestine the valvular conniventes are voluminous; in the upper part are irregular areas, greyish white in color, surrounded by a red border; these areas are due to a false membrane, which can be peeled off, leaving a small area of necrosis with much capillary injection and hyperæmia. In the lower part of the ilium is much swelling of the solitary and of minute glands, but no croupous areas. The large intestine, as well as the small, contain fluid contents, greyish, turbid and full of shreds; the follicles are swollen in the upper part. The shreddy masses in the gastric and intestinal contents contain microscopically epithelial cells, round cells, mucous corpuscles and octahedral crystals of arsenic; in the rectum octahedral are found with ease.

² Mitchell, Cook County Hospital Reports, Chicago, 1890.

³ Hertz, Report of Coroner of Cook County, Ill., 1891.

The mesenteric glands are larger than usual. They are soft, and pale-red on the cut surface. The pancreas and spleen are normal in both cases.

The kidneys are also apparently normal, except some capsular adhesions in the man. The liver is about normal in size; on the cut surface the lobules seem large, but the outlines are indistinct, the color yellowish. The heart is of normal size. In both cases there are subendocardial areas of blood extravasation in the left ventricle. The myocardium is pale yellowish gray; it is comparatively flabby, and teased specimens show indistinct transverse striæ. The lungs are œdematous, pleuræ smooth and shining. The brain and the membranes are apparently normal. The pharynx, œsophagus and larynx upon chemical examination showed abundant arsenic in the gastric and intestinal contents, in the liver and in the kidneys of both the man and the woman.

To recapitulate: In these two cases solid arsenic, in the mixture known as Rough on Rats, produced, in twelve and eighteen hours, acute parenchymatous gastritis, acute croupous enteritis with hæmorrhages and capillary hyperæmia, acute follicular enteritis, swelling of the mesenteric glands, cloudy swelling of the liver and of the myocardium, and subendocardial ecchymoses.

Case 2. Arsenical Poisoning.—A wealthy family near Maplewood, in this city, was mysteriously poisoned with arsenic in the early summer of 1890, the father and a man-servant dying. This is the sensational Kuhn tragedy and mystery. The arsenic, probably in solution, was placed either in the coffee or in some pie, or in both, and in spite of appropriate treatment, the cases having been correctly diagnosed ante-mortem by Dr. T. J. Conley, the servant died in twelve hours, and the father in twenty-four. In both these cases, the changes differed considerably from the previous, hence a brief description of the autopsy of the servant will be permitted. It was made ten hours post-mortem. The body was well-nourished, muscular, about 35 years old. There were no external marks of violence. The peritoneal cavity was empty and the peritoneum normal. The stomach was somewhat dilated, and hanging low down, it contained 20 ozs. of grayish, granular fluid; the mucous membrane is very much swollen, covered with large flakes of viscid mucus; its tissue is the seat of innumerable hæmorrhages, occurring singly and in crops—these hæmorrhages occupy the summit of the folds as well as the depressions between them. The submucosa is swollen also, and distended with clear fluid. The contents of the duodenum are watery, its mucous and submucous coat are greatly swollen, and here and there are occasional hæmorrhages. The jejunum and ileum contain about 18 ozs. of faintly yellowish fluid, which looks like rice water. The swelling diminishes from above downward, while the

solitary and agminate follicles are considerably enlarged near the ileo-cæcal valve. The mucous membrane of the large intestine is pale, not much swollen, covered with strands of mucus; the contents rice-water like. The mesenteric glands are swollen. The liver shows indications of cloudy swelling. The kidneys seem normal. The respiratory organs and the upper parts of the intestinal tract are intact; the heart shows nothing abnormal, and the brain and its membranes show no structural changes.

Arsenic in abundant quantities was demonstrated by Prof. Haines in the gastro-intestinal contents, and in the liver and the kidneys.

To recapitulate: In this case the changes consisted of acute catarrh of the stomach and the small intestine, with œdema of the gastric and duodenal submucosa, hæmorrhages, follicular swelling, and a simple acute catarrh of the large intestine, with a commencing parenchymatous degeneration of the liver.

Case 3. Suicidal Paris Green Poisoning.—An old man swallowed a quantity of Paris green, and died in about ten hours. Autopsy in ten hours. Lips livid, skin over face pale, mouth and œsophagus normal, mucous membrane of pharynx swollen and quite red. The stomach is considerably dilated with gas, and fluid of a bluish or greenish tint; upon the inner surface are masses of mucus with green particles in it. The mucosa is greatly swollen and thrown into numerous folds, in it are numerous hæmorrhages, the free surface of which appears eroded. The contents of the small intestine show particles of green throughout the entire extent; the mucosa is much swollen, in some places opaque areas of varying size and form, with slight superficial loss of substance, can be observed; one of these areas is about 3 inches long, but does not include in all its parts the entire mucous membrane. In some parts there are fine hæmorrhages in the vicinity of these areas, and there is a general capillary hyperæmia. The solitary glands are markedly prominent, but the increase in the Peyer's patches is not so marked. In the cæcum the poison is macroscopically visible, but not any further into the large intestine, the mucous membrane of which is pale and free from corrosion. The liver measures $25 \times 18 \times 16 \times 6\frac{1}{2} \times 3\frac{1}{2}$. It is very flabby, the capsule is smooth, the parenchyma is brownish in color, with yellow spots, and the lobules are enlarged, with indistinct outlines and a congested centre. The kidneys are of about normal size, in the cortex are found numerous pin head size hæmorrhages. The mucous membrane of the ureters and of the bladder is swollen, and shows a few ecchymoses. The myocardium is opaque, yellowish-red, and underneath the endocardium of the left ventricle are many extravasations. The lungs and pleuræ are quite normal, ditto brain.

Recapitulation.—Acute gastro intestinal catarrh with hæmorrhage, erosions and capillary hyperæmia; acute parenchymatous nephritis with swelling of and extravasation into urethral and vesical mucous membranes; acute parenchymatous myocarditis, subendocardial extravasation.

If we now pass in brief review the various changes that may be produced by arsenic it will at once become very evident that they are exceedingly fitful and freakish, subject to marked variation in intensity and extent, not bearing a constant relation to the quantity introduced nor the time elapsing between the ingestion and the fatal end, so that a general description of all the changes that may be produced would rarely apply to a single concrete case.

Commencing with the mouth and the upper part of the digestive tract, it may be said as a general rule that arsenic does not produce any changes upon the mucous membrane of the pharynx and œsophagus, when taken in its usual form, although Woodman and Tidy⁴ state that congestion of the gullet, mouth and windpipe from the application of the poison during vomiting, is general. Externally the stomach and intestines do not usually present any changes, although it is usual to find the stomach somewhat dilated with gas and fluid, but the serous surface is almost always smooth and shining while the amount of blood in the subserous veins may vary within wide limits; the authors just quoted state that inflammation of the peritoneum is occasionally found, but except in very rare cases where it is secondary to perforation of the stomach, this does not seem to have been described by other reliable observers. The contents of the stomach are usually a little bloody with considerable adherent viscid mucus; the mucous membrane is usually swollen, in some places it may be markedly opaque and greyish yellow in color. The epithelial cells under the microscope showing typical parenchymatous degeneration; at times it may be the seat of areas of capillary injection and hæmorrhages, especially in the cardiac and pyloric regions, and small areas of necrosis can be observed on the surface of the hæmorrhagic districts; then there may be croupous areas, that is, places covered with a more or less easily removable greyish membrane, which microscopically shows a fibrinous network entangling mucous corpuscles, epithelial and round cells and, often, octahedral crystals of arsenic; the submucosa may be doubly thickened from œdema; perforation and gangrene are very rare occurrences, but cases are stated to be on record. Similar processes may continue into the duodenum and a considerable distance into the small intestine; usually the contents of the small intestine are rice-water like; the mucous membrane may show catarrhal enteritis, areas of croupous inflammation together

with hæmorrhages, districts of capillary hyperæmia and areas of necrosis and erosion; the follicles, solitary and agminate glands may be and very frequently are enlarged either from œdema or from cell multiplication. The mucous membrane of the large intestine is also often the seat of a catarrhal or follicular enteritis with swelling of the mucosa, and the production of viscid mucus; octahedrals may be found microscopically, and Woodman and Tidy state that the rectum is invariably the seat of an acute inflammation, a statement that seems to me to be too sweeping.

Simple hyperæmia of the intestinal and gastric mucous membrane is exactly similar in appearance, whether it owes its existence to physiological or to pathological conditions. The differentiation will depend upon the nature of the secretion and upon the appearance of the interstitial tissue and the lymphatic apparatus. Acute gastric catarrh is always accompanied with the production of a viscid, glairy, clear mucus; acute intestinal catarrh results in the outpouring of a considerable amount of watery fluid; an acute catarrh of the large intestine, on the other hand, again leads to the production of viscid mucus. If a few hours pass between the commencement of the inflammation and death, and especially if the irritant be of some intensity, it nearly always leads to inflammatory œdema of the mucosa and submucosa, and to considerable increase in the size of the regional lymphatic glands.

The hæmorrhages and the hæmorrhagic erosions will be more marked in cases of severe and prolonged vomiting, and in cases of poisoning with arsenic in a solid form. The hæmorrhagic necrosis is probably in part due to the production of capillary thrombosis, as shown by Silbermann;⁵ from its point of arrest in the stomach or intestine, arsenic is absorbed into the capillaries and lymphatics; here it causes thrombosis, and a consecutive hæmorrhagic necrosis may follow, the tissue succumbing completely to the action of the gastric juice and to the attack of intestinal microbes. The croupous exudate seems to be formed only when solid arsenic has been taken; Lesser⁶ states expressly that he has never observed it except in such instances, but not invariably even then; this is a point of some practical importance.

The mesenteric glands are usually swollen, red and soft, partaking of the general regional lymphatic enlargement.

Cloudy swelling and fatty degeneration are found frequently in the liver, though Woodman and Tidy⁷ state that no post-mortem appearances are found in this organ, but Lesser⁸ and Caspar⁸ have observed such changes in eighteen, in nine

⁵ Virchow's Archiv., Band. 117.

⁶ Atlas der Gerichtlichen Medicin, Berlin, 1888.

⁷ Loc. Cit.

⁸ Text-Book of Path. Anatomy and Pathogenesis, New York, 1887.

and in seven hours, the liver being flabby, increased, perhaps, in size, the parenchyma being opaque and brownish, with yellow areas, enlarged lobules with indistinct outlines, congested centers, and pale, cortical zones; microscopically, the cells are large and granular, with indistinct nuclei; acetic acid may dissolve some of the granules, and boiling alcohol and ether others. According to Ziegler, various poisons, such as phosphorus, arsenic and the ferments which produce fever, may, like imperfect oxygenation, lead to disintegration of the albumen of the tissues, and so to fatty degeneration.

The kidneys may show no changes at all, or they may be seat of parenchymatous degeneration and small cortical hæmorrhages, the urinary sediment corresponding exactly to that in acute nephritis generally; the ureteral and vesical mucous membranes may also be swollen, and show hæmorrhagic extravasations in occasional instances.

The heart is often the seat of a parenchymatous myocarditis, especially of the muscles of the left ventricle, which are soft and flabby in consistence, grayish-yellow in color on the cut surface, and under the endocardium of the papillary muscles, the microscope showing typical cloudy swelling in the muscle fibres. Underneath the endocardium, especially if not exclusively of the left ventricle, are very frequently found small, irregular shaped, but typical areas of hæmorrhagic extravasation similar to those observed in cases of asphyxia.

Any changes in the lungs directly referable to the action of arsenic cannot be said to occur, except that subpleural hæmorrhages are found quite often. The brain and spinal cord and their membranes are usually negative on microscopic examination, although the arsenic accumulates there in greater quantities than in the other tissues of the body. Arsenic produces well-marked changes in the nerves, the further consideration of which does not belong here. The blood is stated to be dark in color, and to coagulate feebly, and imperfectly collecting in the heart and the large veins, no thick, firm and solid clot being formed. In connection with this, it is interesting to note the experiments of Silbermann,⁹ who, by means of injections of various poisonous substances, and among them, arsenic, into animals, came to the conclusion that many of the clinical phenomena and anatomical changes in arsenical intoxication are directly referable to the power of arsenic to cause a vascular dyscrasia resulting in primary capillary thrombosis, with the formation of secondary stagnation thrombi; he observed the formation of capillary thrombi and antochtonous thrombi in smaller vessels, especially veins, and even in the heart, in animals which were injected with arsenical

solutions and vivisected during the violent symptoms of poisoning that soon followed, arsenic acting as a typical blood poison.

THE LEGAL ASPECTS OF ARSENICAL POISONING.

Presented before the Medico-Legal Society of Chicago, Oct. 3, 1891.

By the HON. C. G. NEELY, (Assistant States Attorney.)

The papers which have preceded what I wish to say have dealt with the question of arsenical poisoning from its medical manifestations, and with scientific truth, not theory but fact. After listening to the papers and remarks made here this evening it is not strange to me that it is so difficult to prove murder by arsenical poisoning.

In viewing arsenical poisoning from a legal standpoint you will have to understand one or two things: Every crime on our statute books is characterized by certain essential and necessary elements, which, as a matter of course, must be proved and which generally are capable of proof; not that proof can always be made, but proof is possible. For instance, you take a case where the charge is larceny, we speak of it as larceny as lawyers, it is simply stealing, and the gist of the larceny or stealing is to be taken as contradistinguished from accident, mistake or the like. The gist of burglary is the entering into any building with force or without force, with the intent to commit a felony or larceny. The gist of murder is malice, the unlawful killing of a human being with malice aforethought.

So you can see from these illustrations that what a prosecutor must do is to prove what he charges. You gentlemen of the medical profession dealing in scientific truths as you are, are not content with theory at all. In that respect the legal profession meets you and greets you. It is one thing to charge an offense and it is another and entirely different thing to prove it, I do not care whether it is a charge made in the form of an indictment in a criminal proceeding, or whether it is a libel on the street or anywhere else. The older men grow the more they learn; it is one thing to assert and another thing to prove. Truth and evidence get mixed. I presume that lawyers and courts have as much trouble in making the laity, if I may so term the uninitiated, understand the difference between evidence and proof as physicians do with having the people among whom they practice understand the difference between a genuine and thoroughly educated medical man and an advertising quack.

Evidence is that which tends to prove a thing, a means by which proof is established, and proof is the natural, logical result of evidence. And oftentimes lawyers are annoyed, particularly those of the prosecution, by people saying, "Why, this was proved." It was not! It was attempt-

⁹ Virchow's Archiv.

ed to be proven and failed, but they did not know the difference. When a prosecutor begins a case where there is a charge made that death has been occasioned by poisoning, or an attempt had been made to occasion death by poisoning, he is put very much in the same position as a physician or surgeon when called to the operating table or sick room. The first thing the physician has to do is to diagnose the disease, in other words find out what is the matter. The physician calls it diagnosis, the family asks, what's the matter, they mean the same thing. The lawyer when he commences a prosecution on a charge of arsenical poisoning, or death by any poisoning, must at once determine what means he shall use to get at the truth. Now it is easy ordinarily, when a crime is charged, to find some circumstance connected with the perpetration of the offense that at least indicates where the truth lies. But when you take a case of arsenical poisoning the very statement of the charge indicates the manner of the procedure; the plain English of it is, this man was killed by being poisoned with arsenic, prove it. How are you going to begin to prove it? You have heard to-night what these gentlemen have said who understand medicine and the treatment of disease. I cannot speak on that question at all, but when you begin to cast about for a line of procedure in the prosecution of a case of that sort, the first thing to be done is to prove that the person is dead and was killed by poison. If the indictment charges arsenical poisoning and you prove any poison, that is sufficient. If death was caused by poisoning, the question arises, what poison? Suppose you suspect arsenic, you can see the legal profession is at once thrown right into the hands and arms of the medical fraternity. The whole proof in a poisoning case rests on the medical profession. It is not enough to say that a man is dead, that he did not die of natural disease, that there was no violence used upon him. It is not enough to say that some person had motive enough to kill him, or that some person threatened to kill him, nothing will suffice except to prove that he was poisoned, and that beyond a reasonable doubt. Not by mere preponderance of the evidence, not by mere suspicion, but what was actually the fact beyond a reasonable doubt. The first question then is, was the drug used a poison, a noxious drug? Who can tell that? Lawyers can't tell it, the ordinary witness cannot tell it. If it is a burglary case any witness can tell what was done; it does not take expert testimony to prove that a revolver is a deadly weapon, but in this sort of case the first thing is, was this drug a deadly poison, and it requires an expert to prove it, some one who understands the drug. In beginning his examination the physician stands very close to the lawyer. He looks into the stomach, liver, kid-

neys for poison and he finds it. Without taking more time he is satisfied that this poison is arsenic or some noxious drug, then the question arises immediately, how was it administered. A man shoots another and people can say, he shot him, he stood up and shot him, said he was going to shoot him. This is easy. But how was that poison given, who administered it, is the great question for proof from a legal standpoint, in a case of poisoning. There comes the expert again, the physician or the chemist, and when he begins to determine how it was administered he calculates first on the amount given, whether or not it was an overdose imprudently taken by the person himself, or whether it was an accumulation of proper doses given at regular intervals, having massed together and occasioned death. The traces left in the organ itself usually throw some light on the subject, and in those cases where death is instantaneous, as from prussic acid, the position of the body throws great light on the question as to whether it was self-administered or not. The first question is, was there poison enough to kill, then did the man take it to kill himself or was it administered by somebody else. Suppose the quantity negatives the thought that it was self-administered, then the question is, who did administer it? The ordinary laws of proof come in there. Suppose it is admitted by the defense that he did administer it, but in the proper way and for proper purposes. Suppose it is claimed that it was given accidentally by a person unacquainted with the drug. Suppose it is contended that it was given by a physician acquainted with the drug, or by some one else who understood the drug, but by mistake too large a quantity was given. If it is admitted that the defendant, or accused person gave it, but he claims that he did it properly under medical advice and direction, then is it proper to show that he has poisoned other people. Any legal writer would say that it is never proper to establish any other offense than the one which is being tried. But when the idea is advanced that the poison has been given accidentally, or with good purpose by mistake, it is proper to introduce evidence of other poisonings to rebut the theory of accident, it not being possible that a man should poison one case after another from accident.

It is a singular fact, hinted at in some of the papers to-night, that poisonings do not occur singly, but they are nearly always in a series. A man poisoning his wife began by poisoning his first wife and his child. In the Newland case first the father was taken, then the mother and the children. A person giving a drug which we do not know the nature of, with proper medical advice, from good motives, without wicked intent, would be guilty of manslaughter for carelessness.

After these primary conditions are out of the

way and it is decided that the accused gave the poison, the question arises, how are you going to prove that he gave it? Did he have the article, or did he manufacture it. You look at the materials out of which the poison is compounded. If it is a fact that he has manufactured the drug, it is competent for the prosecution to show that he did and had the vessels for compounding it in his possession. It is competent for him to show that he had them in the line of his business, and that it was nothing unusual for him to make poisons. Another question which arises is this: It is not enough to prove that the man is dead, and that poison was given, but it must be shown that the poison found in the body was put there before death or before the body was exhumed. In a large number of cases the body is buried and suspicion averted. Then, as Dr. Hektoen said, the crime is often buried by the undertaker who has used embalming fluid in the body. If the body is exhumed and examined, then the question comes up, has it been tampered with by strangers. I cite this outline briefly so that you can see how difficult it is to prove beyond a reasonable doubt that a man was poisoned wickedly and maliciously. Now passing to malice, how are you going to prove it? You have got to the point where the medical expert testimony is that the man was poisoned, the drug had been detected, its character is known and the indications are that it was a case of poisoning, not suicide, and that the accused did it, that is proven. You are only about one third started; now the question is, why did he do it? Suppose you show that he did not do it from any good motives, but negative intention does not prove anything. Suppose the prosecution proves that it was done maliciously. Suppose it is the case that the accused went out of his way to be in the company of the deceased, insisted in preparing food for him but abstained from eating or drinking any of that food. I believe it is a fact that in a case of this sort the legal profession always welcomes the testimony of the expert. I suppose it is a fact that when a man dies and you discover arsenic in large quantities even in the body, the best that can be said is that the strong possibilities are that arsenic caused death, but no man actually knows whether he died from the poison so introduced or whether he died from disease, unless it is a very marked case.

On the question of malice, if it is proved that the person accused administered the poison, that he knew it was a deadly poison; if he disclaims the knowledge and it is shown that he did it, then the inference of guilty knowledge or malicious intent is strong indeed. I presented the Newland case to the jury that tried Mamie Starr for murder. In the presentation of the case the fact that the father, Mr. Newland, died, came out fully, but in that case there were not the usual

difficulties occurring. I ought to say in passing that one of the proofs of wholesale malice, one of the proofs of intent that negatives and rebuts the idea of accident, is that the poison employed is one not ordinarily in family use. Not such a medicine as might be easily mistaken, not something that might be given in too large a dose with no intention to harm, but they nearly always employ some medicine that is used for the purpose of attacking life. In the case of the Newlands this girl had gone to the family and staid there through the day. She was kindly treated and had no occasion to find fault; she had no ill will against the family and apparently no motive. I want to suggest that motive and intent are separate and distinct. Motive is that which moves the person to do the thing and leads him to make up his intention. Intent is the purpose for which he does it. So while we do not have to prove motive, it is always of great assistance, but in that case there was apparently no motive. It was proven that arsenic was used, because the girl asked for 25 cents just before supper and went to the drug store to get some toothache medicine. At the drug store she asked for rough on rats, and asked the druggist if he had anything else that would kill rats. He said he had, but that rough on rats was more poisonous and would kill them quicker. She bought a box of rough on rats and some chewing gum, paying 15 cents for them. She asked if she should get supper and opened a can of corn, and, as she herself said, took a pinch out of this box of rough on rats and put it in the corn. She did not taste the corn. The testimony was that they complained of a burning sensation in the roof of the mouth, and thirst, and they began leaving the table, and the mother was up stairs vomiting within 15 minutes of the time she sat down to the table. When the family began to be sick, first the mother, then the father, then the son and the daughter, all that composed the family, this girl was found in a crouching position in the hall, and when the daughter went out and said to her, "Mamie, what did you put in the corn; did you put pepper in it?" she appeared to be terror-stricken, and denied having put anything in it. She disappeared, and when the doctor came and looked around for arsenical poison, the girl could not be found. She testified that she took the box of rough on rats, put it in her apron and threw it away. She said she put it in the corn for the purpose of seeing what the effect would be.

I speak of that case because you can see from the statement what the legal aspects of a case of poisoning are, whether it is arsenical poisoning or any other. I want to say that we are glad to see physicians come into court because their testimony is generally concise and to the point, it is direct and positive, and is not the ordinary

rambling indifferent statement of witnesses which by its very carelessness is confusing. Physicians are known to stand for the amelioration of suffering, and the saving of human life. There probably is no profession known among men where its members stand so close to the home circle as does the physician, the ministry not excepted. The physician stands in the home at birth, in sickness, and in death. The place where the physician as a professional man meets the lawyer on the highest grounds of scientific truth is in a court of justice, where the question is, was the death of the deceased occasioned by poisoning, and if so, what shall be done in order that the crime may be punished and justice done? and it is about the only time and place I know of where a physician is called upon to make a statement or do anything against human life and liberty, and he does it then in the interest of justice.

I thank you, Mr. President and members of the Society, for the honor you have done me in asking me to speak to you and for the attention with which you have listened to my remarks, and I assure you that the work of the physician and lawyer in our courts of justice on the higher grounds of scientific truth is a work that is welcomed by both professions alike.

Discussion of Papers.

Dr. L. H. Metler: I would like to suggest for the consideration of the chemists present, a very shrewd suggestion of Mott, of New York. This question was discussed before the Medico-Legal Society of that city, and he stated that oftentimes the presence of the poison is proved, but the question is, Did the patient die of the poison? Prof. Mott suggested to the chemists that if they could find the chemical or physiological combination between the living protoplasm and the arsenic, it would be a grand discovery, and would throw great light on these cases where there is difficulty in deciding whether the patient died of arsenical poisoning, or whether the arsenic was thrown into the body after death. If such a combination could be found, if the poison were taken during life, some part of the body would show the combination, and would go a great way towards solving the difficulty. I was much interested in Prof. Mott's suggestion, and presented a paper to that Society, in which I showed that if even such a suggestion were carried out, it would be uncertain, because physiology tells us that we do not know just when death occurs in the whole body. Rigor mortis is supposed to be similar to muscular contractions by many leading physiologists, and if that be true, if the arsenic is used in an embalming fluid thrown into the body, there will be a possibility of the combination of protoplasm with the arsenic.

Dr. F. Formanack: I have listened to the discussion of these papers with a great deal of interest. During the last four years I have had about five cases of arsenical poisoning by Paris green, one of which died. In regard to the embalming fluid, I would say that I was called to a case by an undertaker a few days ago, where a mau was supposed to have died from taking Paris green. He was insured, and the policy was such that if he had committed suicide the insurance would not be paid, so I was requested by the relatives to make an autopsy. It seems that the coroner had made a post-mortem, and the jury had given a verdict of suicide by taking Paris green. When I got there I found that the undertaker had used this arsenical fluid, so of course it was of no use to make even a chemical examination of the organs. This was a medico legal case where the embalming fluid should not have been used.

Dr. J. J. M. Augear: I remember distinctly that Prof. Blaney, in a lecture upon arsenic, stated that we had better not administer an emetic, or at least not until we had put large quantities of milk and eggs, or something else, into the stomach, to gather up the material, and if the emetic were administered then, we would be likely to get out all the arsenic. Some such fact has come out incidentally this evening, but I would like to bring it out more pointedly. While Prof. Blaney was lecturing on arsenic and using it in solution on his table, by mistake he took up the wrong tumbler and drank it off. He discovered that he had swallowed the arsenical preparation, and asked one of the boys in the class to get him some eggs. He cracked three or four and swallowed them, then went on with his lecture, and as soon as it was over, he went into the laboratory and took an emetic. I carried out that suggestion some time ago. I was called to a woman who had taken arsenic for suicidal purposes. Vomiting had commenced, and I ordered all the milk she could drink. She would swallow a cup of milk and it would come right up; this was done repeatedly, and the result was favorable.

Another point has been hinted at to-night, but not brought out as prominently as I would like to have it—that is, the care with which the material from the body is preserved. I know of one case in the rural districts, where a post mortem was had and the contents of the stomach thrown away, and the stomach put into an old tin can and sent off to be tested. I have known a number of cases where it would have been utterly impossible for an attorney, or a medical man or a chemist, to go before a jury and state positively that there had been no opportunity whatever for a vicious person to put arsenic into the material, and as a matter of course that would vitiate the whole proof.

Dr. H. T. Tillotson: The question of embalming fluid which has been brought up to-night reminds me of a case I had a year ago. A young lady at a party partook of cake, and some time during the night she began vomiting, and had colicky pains, with other symptoms of poisoning, and in about thirty hours she died. I took it upon myself to look after the cake question, and while I was out the undertaker was called in, and embalmed the body. I called him up by telephone to ascertain why he did it so soon, and his excuse was that he was asked by the family to do so. I wanted to know why he did not wait for the death certificate, and he said he never had and never would wait for a death certificate. I inquired of other undertakers, and they claimed the same thing, they will embalm the body as soon as the friends ask them to do so, and will not wait for a death certificate.

Dr. A. W. Baer: About a year ago I was called to see a young man who had taken poison, and as I was called in a great hurry, I neglected to take a stomach pump. I asked for hot water and mustard, but they did not have any, and I sent to a saloon for some mustard. The young man, in the meantime, laid in a comatose condition. I mixed the water and mustard, and attempted to get it down him, but was unable to do so, and thought I had a corpse on my hands. I asked one of the men present to get it down if he could, and I reached for my hypodermic needle, which had some nitroglycerine in it. Without taking very much care, I inserted the needle in the muscles underneath the arm, and the man jerked the arm away from the needle himself, and it took four men to hold him on the bed, to keep him from getting up and killing the doctor. I then succeeded in getting the mustard down. He acknowledged that he took a white powder, which I thought was arsenic, but it was the effect of the nitroglycerine on the comatose condition I wished to call attention to. I think the condition was due to arsenic, and not to morphine, for it was an hour after he had taken the drug, and if he had taken the dose he did of morphine, it would have had a different effect on him.

Dr. Daniel T. Nelson, in closing the discussion, said: I will only speak of one or two points. Dr. Hektoen spoke, I think, truthfully of the contents of the stomach and intestines looking like rice-water discharges, which are familiar to all physicians in cholera, and the appearance of the patient, it seems to me, is so much like cholera as to suggest the question propounded by Dr. Wescott as to whether the arsenic does not affect profoundly the nervous system, as the cholera poison does. I am inclined to believe with Dr. Wescott that, primarily, the coma and convulsions are due to the direct effect of the poison upon the nerve centers of the brain and spinal

cord, and hence the paralysis in chronic cases; but possibly, subsequently, before death, there may be convulsions of a uremic character.

In the autopsies described by Dr. Hektoen, one point seemed to me especially characteristic and interesting. The thirst and dryness of the throat and fauces before death have been noted by all; and yet, after death, there is little to be seen of pathological change there, and I believe this is true also in cholera.

One suggestion as to an antidote. Dyalized iron is perhaps as efficient as the wet hydrate of sesquioxide; it is certainly very convenient, and can usually be found in the drug stores; can be used without preparation, and can be given in any dose safely.

The following resolutions were unanimously adopted:

WHEREAS, The science of Forensic medicine at the present time demands such exactness and thoroughness in the post-mortem examinations of medico-legal cases as to always require greater facilities than those presented in a private dwelling or common undertaking establishment; therefore, be it

Resolved, By the Medico-Legal Society of Chicago, that the coroner of Cook County be urged to send all bodies requiring a post mortem examination to the new county morgue, and that such facilities as the importance of the work demands be arranged for in the morgue building, so as to make it as complete a medico-legal institution as possible under the circumstances. And further:

WHEREAS, There are no restrictions upon the sale of arsenic, which often facilitates the commission of crime; and

WHEREAS, The use of embalming fluid containing arsenic by undertakers obscures cases of poisoning by this drug, is not necessary, and causes the miscarriage of justice, it is

Resolved, That the sale of arsenic should be strictly regulated by law, and the use of arsenical embalming fluids should be entirely prohibited.

ARCHIBALD CHURCH, M.D.,
Secretary.

DOMESTIC CORRESPONDENCE.

HOT SPRINGS, ARK., Nov. 10, 1891.

Editor The Journal, Chicago, Ill.:

Desirous of calling the attention of the medical profession to the anomalous condition of things existing at this place, I ask the publication in THE JOURNAL of such facts as are given herewith:

This town is sustained *entirely* by visitors coming here in search of health or pleasure, mostly the former. There is literally nothing else. The facility with which the invalid can be gulled on his arrival here is startlingly wonderful, and opens a very fine field for sharpers, who are nominally in the profession, aided by ropers who meet the victims on the railroad trains and beguile them first to a boarding house and bath house, and finally to the doctor's office to be robbed and maltreated.

This evil has assumed such outrageous proportions, that the few practitioners here who take the code for

their guide, are compelled in self-defense to cast about for some method by which they may hope for success in at least mitigating the evil, if not abating the nuisance entirely, both in the interests of humanity and their own.

The condition is "*sui generis*." There is no other place like this. And if we keep within the letter and spirit of the code, we see ourselves daily robbed, to be at last driven out of the field to give place to *other unfortunate ethical men* tempted by the apparently fine prospect, or to be succeeded by the vampires who are already so numerous here. We succeeded in getting passed, by the last Legislature, a law providing for the revocation of license for certain offenses, among which are the subsidizing hotels, and the employment of drummers. The constitutionality of this law is still to be tested; but if it stands, it is very difficult to get cases properly proved up before the medical board which has the jurisdiction, because of the fact that the witnesses—invalid visitors—who are generally desirous of avoiding the notoriety and detention consequent on a summons to court, to say nothing of the possible delay involved—generally prefer to pocket their wrath and lose their money rather than expose themselves to further vexation and the threats of these ropers, who hesitate at nothing.

At one time we circulated a poster on the incoming trains, at considerable expense, but without success, for reasons which would occupy too much space to detail, but which will be given in future if desired.

We cannot fight these men through the press without laying ourselves liable to the charge of advertising ourselves, and we don't know what to do.

Is it possible to put these matters before the profession, with the view and purpose of eliciting discussion? and perhaps some legislation at the next meeting of the American Medical Association, which would allow us to show through the press, or a paper of our own, the actually existing condition, thereby not only sustaining legitimate medicine, but keeping large numbers of invalids out of the hands of irresponsible men.

Did it not occupy too much space, I might add to the foregoing the fact that we have here an organized and recognized medical society; that there are quite a number of doctors here who have heretofore put themselves outside the pale, but who have quit the objectionable methods and desire to be recognized, and as to whom there exists some difference of opinion among members of the Society, arising from the very peculiar condition here (as I said *sui generis*); that the irregulars largely outnumber the regulars, being at present *about* as 16 or 18 to 35 or 45, the figures constantly changing.

A very amusing and interesting article might be written by one disposed to give facts as to the *methods* of these bunko men, and one which would also contain much pathos.

To day I met a man who failed to get a license from the local board, inquiring about an office. As I suppose, he has been to some of the "back counties," where he found an examining board less uncompromising. If I'm correct, this shows the inadequacy of existing law to protect the people and the profession.

Very respectfully, JOHN H. GAINES, M.D.

Case of Supernumerary Mamma.

To the Editor:—The subject of this article is one of some interest; and especially so in this particular case, on account of the size, and as well as the fact, that this mamma, or milk tumor, did not develop until the fifth gestation; and there was no sign of it before that time, so the patient states.

We find quite a number of cases of supernumerary mammae on record, but none with a history like this so far as I know. Bruce has examined 4,000 persons and finds the deformity to be 1.54 per cent., and he says the axillary prolongations are not infrequent and may be mistaken for lymphatic glands; also states the left side is the most common locality of these deformities.

Evy Williams, col., age 39. Married; had six children. Health good. Three years ago, she was delivered of a child and at that time noticed a lump under the left arm pit, which was soft, movable, and not painful or tender on pressure or sore, as she states.

One month after her delivery she noticed this lump was increasing in size, and it reached the size of a hen egg, and remained so for two years, which was the length of time she nursed the child. After this it seemed to disappear until her next delivery, or three weeks before her confinement, it was about the size of a hen's egg, and continued to grow and was somewhat painful.

The child is now two months old, and you can see in this photo, the size of this extra mamma. You can also see it has no nipple and there is no discharge of milk; but it is somewhat soft and full of milk. I have compared the secretion from this tumor to the milk from the breast, and it is identical, the fat globules are easily made out with microscope. I have made two examinations of this under the microscope.

L. G. HARDMAN.

Harmory Grave, Ga., Nov. 9, 1891.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, NOVEMBER 21, 1891.

ETIOLOGY.

In determining the etiology of a disease, it is particularly important that all the causative factors should be considered. It is not sufficient to assign to one factor an overweening importance, and call it the cause. Let it be admitted that tuberculosis cannot exist without the bacillus tuberculosis, nevertheless, it is only one factor in the etiology of this disease. If this latter statement were not true, this omnipresent bacillus would soon play sad havoc with the human race. These statements are trite, but we submit that the truth which they embody is frequently overlooked, in this age of bacteriological activity. In the investigation of the etiology of a specific disease, it is much easier to determine with accuracy the particular microorganism which may be concerned in its production, than to determine the other factors involved. There is something brilliant about discovering and naming a bacillus; it is accurate and therefore pleasing to the mind, and it is not surprising that a relatively greater importance is accorded to this factor, than to those which are less well established. However, it must be admitted that comprehensiveness here is necessary; nothing less can be admitted as satisfying scientific accuracy. If the natural history of a microorganism could be so thoroughly studied that all the factors favoring its development

should be known, and all the factors retarding its development should likewise be known, and means existed whereby the presence or absence of these factors in the human body could with certainty be determined, then, theoretically at least the complete etiology of the disease determined by this microorganism would be known. But this ideal solution of the problem is far in the future; if, indeed, it ever be realized.

For the present, at least, we must be content with the light which can be thrown on the subject by the clinic, and it is surprising as well as gratifying, to see how well clinicians have done their work, and much information, often of a curious nature, has been obtained from this source.

The germ of scarlatina has as yet escaped the researches of the bacteriologists, but whatever may hereafter be shown to be the size and shape of this germ, whatever be its reactions with stains, or its peculiarities of growth, or its action upon various food-stuffs, clinicians know that it has a strong hold on life, and finds a favorable nidus in clothing, furniture, toys, and wall-paper, and many other things. They also know that it has a peculiar predilection for early life—so much so that nearly half the cases are found between 1 and 4 years of age. Long before the discovery of the KOCH-EBERTH bacillus, clinicians knew that the stools of typhoid patients contained the poison of the disease, and that drinking-water contaminated with these stools was the most common means of transmitting the disease. And this information is much more valuable to-day than any which has been furnished by the more exact knowledge of the bacillus, particularly since the means of recognizing the germ have been called in question.

It is useless to multiply instances showing the remarkable accuracy and wide extent of the additions to etiology which clinical research has made. The field for clinical work in etiology has by no means been exhausted. Much remains to be done. The method, however, is a slow one, as opportunities must be waited for, and when they come their significance must be at once recognized, or the chance is lost. This is very different from laboratory work, where a definite series of experiments is planned, at once carried out, and the results used to modify the conditions of subsequent experiments. Such

work as this is to a large extent mechanical, and we are sorry to say that many of its advocates, dazzled by the rapid acquisition of knowledge by its methods, have put themselves in a position of assumed superiority, and regard the clinician with mingled pity and contempt. It should never be forgotten, however, that all laboratory results must ultimately be tried for their sufficiency and comprehensiveness, by the clinical test.

Certain of the work in etiology which can best be done by the clinician, is work which can only be done in small communities. To trace the origin of a case of infectious disease with certainty, it must be possible to trace it to a single source, and to exclude positively all other possible sources. Such conditions are never found in large cities, but occasionally may be met in small communities, and it is the opportunity as well as the duty of the medical men who live in small communities, to watch for these cases, observe closely, trace carefully, and report for the benefit of the profession. From the nature of the subject, while a single report is valuable, a multitude of such reports, whether from the same or different sources, has a much greater value, and no one should hesitate to assist in the multiplication of such facts. In a hamlet of two or three hundred people, it is possible to know exactly whether an infectious disease exists or not. When the first case of infectious disease breaks out in such a community, it is usually easy to find the particular individual who has been the means of transmitting the poison. Then should be noted all the circumstances concerning such transmission. Over how great a distance was the poison conveyed; how did the transmitter of the disease travel; was travel for miles in an open wagon insufficient to dissipate the poison; how long was the individual exposed to the first case, and in what sort of contact with him was the one who subsequently developed the disease; what was the stage of the disease when the carrier got the poison from it. This last item is of particular importance. To this day it is not known with certainty whether or not scarlet fever can be transmitted from a patient in its very earliest stages, and yet every physician wishes sincerely that he knew.

It is not our object to review with any completeness the etiological factors which may be established by clinical observation, but rather to plead for the recognition of a broader and more

comprehensive etiology than is the custom to-day; to emphasize the value and importance of clinical research in solving the problems of etiology; to show that some of these problems can only be solved by the medical men in small communities; and to enlist the services of men so situated in making observations of this character. We shall be pleased to publish any communications from our readers on this line of work, which shall show that they have carefully traced a case to its origin, and have excluded possible sources of error.

DIPHTHERIA.

This acute, infectious disease is quite prevalent in nearly all centers of population; according to its nature, attacking the children in some families and in some districts with fatal malignancy, and in others showing itself only in the mildest form of the disease. The general prevalence of diphtheria very naturally furnishes a most interesting theme for discussion at medical society meetings.

The KLEBS-LOEFLER bacillus is believed to be the active agent in propagating the disease; also, that the first manifestation is local, and that the immediate absorption of the poisonous chemical products which are developed in the original nidus are productive of the well-known constitutional symptoms so frequently found in a sub-normal temperature, feeble circulation, nervous exhaustion and malaise.

It is in the characteristic exudative membrane formed in the throat, nostrils and trachea that the bacillus is found, while the accompanying œdema and swelling of the parts in this locality at once threatens the life of the patient. The option of the operation of tracheotomy or the insertion of one of O'DWYERS' laryngeal tubes is frequently presented, the latter being, by all odds, the one most generally selected. The physician who inserts a tube should be prepared to perform tracheotomy, as a condition demanding the one is very close to the border line of the other.

From the first onset of the disease until complete convalescence is established, rest in a recumbent posture should be insisted upon. Simple and easily digested nutrients should be given every two or three hours, only limiting the

amount of nutritious food ingested by the capacity of the stomach for its assimilation and digestion.

Alcoholic stimulants are called for to the extent of tolerance; heroic doses are necessary to counteract the depressing effects of the poison of the disease.

A topical application to the affected part of a solution of one grain of bichloride of mercury, dissolved in four ounces of per oxide of hydrogen, as first recommended by Dr. Waxham, of this city, is a most effectual remedy.

In this connection, attention is directed to the easy and complete solubility of bichloride of mercury in glycerine, after which dilution to any extent may be conveniently made.

The acute symptoms of an attack of diphtheria being tided over, the avoidance of disastrous sequelæ may often be accomplished by a seemingly long continuance of the patient in a restful, recumbent posture, and a keeping up of the stimulants and extra diet.

From the very first indication of the presence of the disease, the patient should be as thoroughly isolated as possible; upon the perfection of this isolation or quarantine of the patient depends the ability to control the spread of the disease, and no matter how many cases a physician may have at one time, his efforts at establishing a complete quarantine of each one should never flag.

All expectoration and discharges from the throat, nose and mouth should be received upon paper napkins or pieces of tissue paper, and immediately burned. The soft Japanese paper napkins, which are so common and easily obtained, answer an admirable purpose as handkerchiefs for the sick of diphtheria or other infectious disease. Being inexpensive, after using they should be immediately burned.

Asepsis and antisepsis in the treatment of infectious diseases are just as important to the physician as to the surgeon in capital operations.

TREATMENT OF THE INSANE IN GENERAL HOSPITALS.

As matters stand at present, there are two crying evils, if not more, in the provision for the care and treatment of the insane in nearly all parts of this country. One is the deficiency of

knowledge on the part of general practitioners, the other, deficiency of accommodations in the special hospitals provided for this class of invalids. It scarcely need be said that, in most of the medical schools of this country, opportunities for the study of insanity are either non-existent, or of the most meagre sort. Where any attempt is made at systematic instruction on this subject, it is usually by didactic lectures, without any clinical illustration, and it is safe to say that a large majority of graduates of our medical colleges have as good as no acquaintance with insanity, and only the most vague and indefinite ideas in regard to its treatment. As a rule, they are sensible of their deficiencies in this direction, and are apt to advise, in cases that do not show a tendency to pretty prompt recovery, that the patient should be sent to a hospital, but this is only a partial mitigation of the evil. The decision whether or not a patient shall be removed from his home and friends, and deprived of his liberty, is one that calls for a great deal of discrimination. We do not at all share the belief that the confinement of sane persons in asylums for the insane, either wilfully or through ignorance, is a common thing; on the contrary, we believe that the mistake is much more often made of allowing persons to go at large who ought to be restrained, both in their own interest and that of others. It does, however, sometimes happen that persons who are unquestionably insane are subjected to the odium and distress involved in an official declaration of insanity, when under judicious treatment they might have recovered equally well at home, and in many cases the chances of recovery are imperilled by injudicious treatment.

On the other hand, when it is decided to be best that the patient should be placed in a hospital, there is often most unfortunate delay owing to the overcrowding of these institutions. In almost every State in the Union, the accommodations for the insane fall far short of what is needed; the hospitals become clogged with an accumulation of chronic cases, and, as a consequence, the admission of acute cases is delayed till the time is past in which there is hope of recovery.

Both of these evils might be partially remedied by a measure which has been proposed in various quarters, and which has recently been strong-

ly urged by DR. J. BATTY TUKE, in an address delivered before the Royal Academy of Medicine of Ireland, and published in the *British Medical Journal*, the establishment of small wards for acute cases of insanity in connection with general hospitals. This would give medical students an opportunity for clinical instruction and experience which would be of great value to them and their patients in practice, and would increase the opportunities for prompt hospital treatment in cases that require it. If the policy were adhered to of not retaining chronic and, presumably, incurable patients, the stagnation of the population and crowding out of acute by chronic cases might be avoided, and it is probable that many persons would be more ready to send their friends to a general hospital than to an asylum for the insane.

The principal objection to such a plan is the disturbances which would be made by the patients. As DR. TUKE says, however, this objection applies with greater force to wards for delirium tremens, which is, in fact, one of the most objectionable forms of insanity in this respect. Such provision for the insane would not at all interfere with the work of the special hospitals, and it could hardly fail to aid in establishing a better understanding between the profession at large and the members of what has hitherto been, unfortunately for all concerned, the most isolated of medical specialties.

HOT SPRINGS, ARK.

We take pleasure in directing the attention of our readers to a letter in this issue of THE JOURNAL from DR. JOHN H. GAINES, president of the Hot Springs Medical Society. As he pertinently says, the professional conditions existing in that locality are anomalous. If every practitioner of regular medicine who has a patient who purposes going to Hot Springs, will give his patient a letter of commendation to some one of reputation in that place, the difficulty will be largely solved.

There are many thousand practitioners who do not know the names of the reputable practitioners at Hot Springs, and for that reason, DR. JELKS, of that place, has his professional card inserted on one of our advertising pages. Look at it; it is only a plain, professional card, with-

out puff or ought else, but the simple fact that it appears in that particular way in this journal is sufficient to endorse him as a reputable man, in good standing in our profession.

Patients going from one place to another, or even heads of families moving from one locality to another, may very properly, in fact, should, be given a letter of introduction and commendation to a reputable practitioner in the place of their destination. Such a course is a manifestation of interest in a patient and patron that is always commendable, and the practice should become as universal as possible.

MISCELLANY.

DR. HIRAM HAYDEN ATWATER, died at Burlington, Vt., aged sixty-three years, on August 19th. His father was a physician at Norfolk, N. J., but the son was educated at Burlington and at Woodstock Medical College, graduating in 1851. He first settled in Brooklyn, N. Y., but in 1861 removed permanently to Vermont. He was pension examiner for many years beginning in 1862. He was health officer of Burlington in 1867, and commissioner of lunacy for two years. Dr. Atwood had a special bent in the direction of obstetrics and was for many years the instructor in that branch in the University of Vermont. He was also one of the medical staff of the Mary Fletcher Hospital. He was the author of various contributions in the Vermont and other medical transactions and the *American Journal of Obstetrics*.

DR. WILLIAM COGSWELL, of Bradford, Mass., who died August 15, at the age of seventy-two years, was an ex-president of his State Medical Society, and the third one of that rank to go over to the majority during the present year,—Drs. Hosmer and Lyman preceding him by only a few weeks or month. His presidency occurred in 1876. He was a member of the Governor's council in the year following, and was twice appointed Medical Examiner for the Essex district, No. 4. He was an occasional contributor to the journals of articles on medico-legal subjects.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from November 7, 1891, to November 13, 1891.

Capt. William R. Hall, Asst. Surgeon U. S. A., relieved from Ft. Schuyler, N. Y., and assigned to duty at Angel Island, Cal. Asst. Surgeon Paul Clenduin, to be Asst. Surgeon with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1874. November 5, 1891.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending November 14, 1891.

P. A. Surgeon J. D. Gatewood, detached from the U. S. S. "Despatch," and granted two months' leave of absence.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Two Weeks Ending November 7, 1891.

Surgeon John Vansant, to proceed to New Orleans, La., as inspector. November 7, 1891.

Surgeon R. P. Murray, to rejoin station at Key West, Fla. October 30, 1891.

P. A. Surgeon C. T. Peckham, to proceed to Memphis, Tenn., as inspector. November 7, 1891.

Asst. Surgeon G. M. Guiteras, to assume command of Gulf Quarantine Station. October 30, 1891.

Asst. Surgeon C. E. Decker, assigned to duty at San Francisco, Cal. October 30, 1891.

APPOINTMENT.

Decker, Charles E., of Michigan, commissioned as Asst. Surgeon by the President. October 27, 1891.

ORIGINAL ARTICLES.

PERSONALITY AS IT AFFECTS THE COURSE OF DRUNKENNESS.

Read before the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY T. L. WRIGHT, M.D.,
OF BELLEFONTAINE, OHIO.

When the elements of the human character are observed in any individual, there will be perceived a number—sometimes more and sometimes less—of intervening, interrupting, interpolating, constitutional characteristics that, abstractly, are not really necessary to the completeness of human nature. And these characteristics, while non-essential, may nevertheless be, so far as the individual is concerned, dominant and decisive in the aggregate and sum total of life's history.

Such peculiarities in the elements of personality indicate imperfections in the constitutional stamina of separate and distinct persons. In some cases they have been impressed upon the individual by ancestry—pointing to a history of disease, or of profound physical injury, or of mental and moral suffering, or inquietude, or disaster. But whatever these lines in men's characters may be, or whence they come, or what they signify and portend—they are present in a state, to some degree obvious to the expert eye, in every human being now inhabiting the earth.

Of the modifying qualities which may thus impress the nature of man, of course only the more obtrusive receive special notice; and of these, the members of the so called *neurotic family* more particularly demand our present attention. For the alcoholic constitution rightfully belongs to this singular group of incapables; and it is interchangeable with all the other distinctive neurotic traits affecting mankind. The simplification of the elements of matter, through its allotropic capabilities, has its parallel in the great family of the *neuroses*. Carbon, we are told, may exist in separate material forms—as in the diamond, in charcoal, in soot, in the carbonates and in other

material substances. In a like manner, one neurotic form may be found masquerading in the features of some other member of the same family—dipsomania being interchangeable with amnesia or epilepsy, or some appearance of insanity; and conversely, these and other neuroses may become—either in the same person, or by heredity, transmuted into dipsomania.

This is not the place to speak of heredity at large. But to deny heredity is to deny parentage. He who cannot perceive both likenesses and contrasts in ancestry and posterity which denote unequivocally lineal descent, is, it seems to me, either blind or of dull apprehension. (a). The cast of the eye, the pose of the head, the set of the ears, the shape of the nose, the arch of the brow, the color and texture of the skin, the "cowlick" of the hair—all these and innumerable other special marks, indicate the power of heredity in the *perceptible* construction of the physical organism. (b). The mental and moral nature, the general disposition and tastes, the family likes and dislikes, the development of particular inclinations and propensities as life progresses, still more strongly if possible, testify to the reality of heredity. (c). Again, diseases tell the unfaltering tale of heredity through the transmission of epilepsy, insanity, heart imperfections, hysteria, dipsomania, somnambulism and a multitude of other undoubted pathological states. They point, not to perceptible and notorious physical conditions of the bodily organism; but they rather denote *imperceptible* changes in the ultimate structure of the brain and nervous system.

The evidence of heredity derived from physical conformation, and also deformation, is *direct*, and comes at once from observations conducted through the perceptive faculties; while the evidence derived through mental and moral properties, and from the transmission and transformation of diseases, is *circumstantial*. It consists of symptoms and indications, and phenomena. It is, therefore, most commonly unimpeachable; for it is composed of coincidences that mutually sustain and illustrate each other.

Heredity, especially the heredity of disease and criminality, is a doctrine as old as humanity—or at least as old as human suffering and guilt. It has been the theme of philosophers and sages

through all the world's history; and it enters largely into the elements of the Christian's hope, as well as the sinner's despair; for, in the disobedience of the progenitor of the human race itself, all mankind were smirched.

The effects of alcohol upon the human constitution may be divided into two classes or groups—those which are obvious to the senses of everybody—and those which are more remote, concealed, and unexpected. Both groups, however, have to do with the whole man—mental, moral, and physical.

Alcohol, for instance, acts openly and within the view of all in exaggerating the egotistic feelings. There is in drunkenness, not only unseemly boasting, and a claim to the possession of qualities in every department of life, superior to others, but there is a tendency to embark in enterprises far beyond the capacity of the person concerned. An habitual indulgence in the use of alcohol, produces a *custom or habit* of asserting pretentious and preposterous claims to excellence and prowess, so that the drinker is eventually degraded into a bragging and besotted imposter and nuisance.

The changes induced in the physiognomy, the speech, and the physical movements of the inebriate are universally recognized. Besides these perceptible bodily disabilities due to alcoholic impressions, there are a number of other notable mishaps that speedily occupy the field of observation. The liver, kidneys, stomach, brain, heart and lungs, show indications of functional—and finally of structural impairment and degeneracy. The interstitial substance throughout the entire organism exhibits a tendency to hyperplasia, although the features of this pathological condition are more pronounced in some localities than in others. Subsequently shrinkage is apt to occur. The consequence is, that a number of organic degenerations are likely to ensue. Nerve fibres in the brain may be implicated and torn in sunder; while the capillaries of the encephalon are, possibly, strangled and obliterated. These, and numberless other physical disasters are amongst the common effects of alcohol. They, and their symptoms, are open to daily inspection and inquiry; and they are liable as a matter of fact, to appear in all constitutions and persons impartially. There are, however, many exceptions of course.

But the usual and open effects of alcohol upon its victims do not stop with the acute or initial stage of inebriety. After a lapse of considerable time, possibly of years, the boasting of the early drinker, so absurd, so empty and frivolous, ceases to merit the name of mere boasting. It descends to the level of habitual and malignant lying. The lofty and assertive egotism, loving and seeking notoriety, is transformed at last, into a sullen and mean selfishness. Stiffened and bent over,

his muscles clamped by the shrinkage and inductions induced by alcohol affecting their sheaths, the chronic inebriate drags himself away with a difficult and crawling movement, shunning the sight and society of men. And the great highway he has traveled between the noisy and boisterous beginning of his career, and its woful conclusion, is the broad road of habitual drunkenness; wherein the daily sot staggers along, lonely and despised.

These are the obvious, the *common* characteristics of alcoholic drunkenness. They are often viewed, superficially, of course, as illustrating *all* the essential traits of alcoholism, physical traits, representing incapacity of action, moral traits, representing incapacity of responsibility, mental traits, representing incapacity of discrimination, reflection, choice.

But in real truth, hidden beneath these direct and sensible displays of the alcoholic power, comprehensive and distinctive as they are, there may be discerned other traits of alcoholism, less obtrusive certainly, but probably not less important and far-reaching. Careful attention will reveal the fact that there are many profound and subtle influences exerted by alcohol upon the nature and welfare of man, that are quite imperceptible to the casual observer.

A good deal has been written, and justly too, upon the effects of the different kinds of alcohol on the human constitution. The constitution here meant is that of the average man; the several effects being due to differences in the article applied, and not to personal idiosyncrasies.

For example, it is known that *ethylic* alcohol (C^2H^5O) produces the agreeable and alluring movements of mind and body, that are so seductive to the inebriate. *Amylic* alcohol however, called also *fusel oil* and *potato spirit* ($C^4H^{12}O$), produces very peculiar and serious consequences when mixed (in impure spirits) with the ethylic or common alcohol. It is to this substance that must be chiefly attributed the muscular instability and trembling, together with the profound poisoning of the brain that characterize delirium tremens.

But the purpose now is, not to apply different alcohols to *similar* constitutions, but to apply the common alcohol, that is, a similar (and least poisonous) alcohol, to *different* constitutions. The desire is to view the effects thence flowing upon mind and morals—upon life and responsibility—rather than upon the grosser physical organism.

It has already been noted that through force of the inevitable accidents of time, and the operations of inimical and destructive agencies, the constitutions of men often represent elements that are not essential to the completeness of human nature. These imperfections and obliquities are frequently present in such force and

number, that they greatly influence, and may even chiefly direct the course of human life. The nature of some of these disturbing constitutional attributes may be seen in the several members of the neurotic family of diseases. It is not necessary to enumerate the individuals composing it. But it may be said that besides the characteristic members, there is a great multitude of persons in whom the neurotic features are imperceptibly shaded off into more or less indefinite degrees of completeness, until in fact, they are obvious only to the eye of the skilful and practiced observer.

In every community the neurotic family has many representatives bearing many names; and there are also relatives of that family that are as yet unnamed. Take for example the man wholly intent on piling up a mountain of wealth; riches that he neither can use, feel, taste, or in any conceivable manner enjoy in this life, nor take with him when he dies.

In such a life there is absolutely no rational object at stake. The man is a "crank." He is possessed of an undoubted neurotic constitution. He is closely connected with the insane family—perhaps a member of it. Not infrequently, amongst his offspring there will appear an idiot, or imbecile, or scrofula, or deformity. Quite commonly there are drunkards—one or more—true dipsomaniacs; and possibly a suicide. It is not exclusively the allurements and opportunities of wealth that so frequently wreck the families of rich men. It is owing, possibly to the inherited neurotic constitution, transmuted in posterity, from the craze of money getting, into the repulsive forms of epilepsy, dipsomania, and the moral insanity of useless and unsatisfying, but universal profligacy. True, sometimes the offspring continues in the paternal groove—and the neurosis of colossal fortune building goes on. But such is not the rule. The neurotic *bent* takes the form of unbalanced nerve equilibrium—*moral insensibility* being connected with *physical hyperæsthesia*. Here is, indeed, sensuality unrestrained.

All this is simply in illustration of the fact, that the neurotic constitution abounds in society more plentifully than generally has been supposed.

The effects of alcohol upon the mind and conduct, no doubt vary in some particulars, in each individual from its effects elsewhere.

But the gross and disgusting qualities of drunkenness that are common to all intoxicated persons, are apt to absorb the attention, to the exclusion of nice, but obscure idiosyncrasies.

There are, however, several specific qualities that alcohol impresses upon certain constitutions, that are not peculiar to drunkenness in general. These in fact are of frequent occurrence—and are of very great significance.

1. Some inebriates invariably exhibit signs of

irrepressible mania when under the influence of alcohol. Here is the true *mania a potu*—a designation often misapplied to delirium tremens. This is a condition readily developed in certain persons. The speech is loud and incessant; nothing can stop it. If admonition or even force is employed, the ceaseless chattering continues unabated. The topic may change, but not the talk. Frequently this state of alcoholic mania displays itself by producing an inclination, almost uncontrollable, to scream at the top of the voice and "make the welkin ring." The inebriate may not be entirely lost to the impropriety of this proceeding, and may pause a brief moment or two, and wonder in his silly mind what people will think of it—whether they will not think he is drunk. But all such sage reflections are speedily lost and swallowed up in the burning desire to "give them one yell anyhow." And so drunkards go up and down the streets, singly or together, shouting, singing and yelling to the utmost limits of their vocal capacity.

But these persons do not always confine their pranks to noisy demonstrations. Very often there appears a strong desire to "smash things."

Windows are broken, doors kicked down, furniture ruined, walls defaced, crockery thrown into the streets, and the spirit of utter destruction reigns supreme. All these things may take place without the slightest incentive of anger or malice. It is an instinctive mania of demolition; and it seems to be simply a process of occupying the attention, and relieving or *staying* morbid cerebral exaltation, by the act of *doing something*. It is scarcely necessary to say that positive and abrupt interference with the movements of an individual who is in such a condition of mania, might prove to be dangerous. It would be liable to arouse a feeling of ungovernable and insane rage.

2. There are many persons in whom alcohol develops a peculiar disposition that is dangerous to any community in which they live. These individuals, when under the influence of alcohol are morose, revengeful, homicidal. Such a spirit may exist in so great a degree of intensity as to amount to actual mania. It is by no means uncommon to read of murders committed in sheer wantonness by persons laboring under intoxication. Such individuals, without offense being given, without a personal acquaintanceship even, or a word being passed either way, will perhaps shoot down some one who, by chance, happens to be in their presence. But the homicidal tendencies of inebriety do not display themselves usually in quite so unexpected and truculent a manner. There are persons in every community who are known to be dangerous characters when drunk; and when they are perceived to be indulging in drink, the public invariably feels that serious trouble is liable to ensue.

These folks may be quiet and pleasant enough when sober, but as drink mounts to their brains, they become implacable and defiant. The memory of old slights and feuds, perhaps latent and for a long time forgotten, suddenly revives. The inebriate asserts that he neither fears nor regards consequences. He would "as soon die as live anyhow." An intoxicated individual possessed of such a disposition, is in a state of mind that is a menace to the public safety. He is really in a condition of insane rage—without limit or abatement—and thinks of nothing but killing and murder as remedies for all his fancied ills.

3. Other men again, possessed of constitutions peculiarly modified by extraneous circumstances, become affected, when under the influence of alcohol, with a nervous condition called by some *alcoholic trance*. Events that take place during the continuance of this remarkable state of the brain and mind, are afterwards but dimly remembered. Sometimes no recollection whatever of them is retained. This mental situation is brought on largely by the anæsthetic property of alcohol. The anæsthesia of alcohol so benumbs the sensibilities of the life of external relation that the inward movements of the organism, to some degree, come into consciousness; at the same time, common sensation and the perceptive faculties remain in abeyance. Ordinarily, in health, the reverse of this is true. Sensations and the perceptive functions engross the attention, and become the subjects of thought, while the inward movements of the organism are unperceived. This peculiar modification of the senses through the influence of alcohol may result in serious consequences. The objective and subjective sensibilities appear sometimes so indefinite, so mixed and intermingled, that one may be mistaken for the other, and the judgment be thereby misled. It is not difficult to see how motive and conduct may be influenced by the misinformation of the mind derived from organic sources.

No sensation or perception is absolutely trustworthy in itself. It must be attested by other senses; and the several comparisons must be weighed and accepted by the judgment before it is received in the mind as undoubted knowledge. But it is obvious that the dim and incomplete suggestions of automatic or subjective life cannot afford these necessary testimonies and proofs of their own accuracy. The mind, therefore, reasoning from the data of a false and impaired consciousness, is dragged from its moorings, and it accepts as facts the unsubstantial phantoms of a wayward and uncurbed imagination.

4. Leaving now the consideration of the peculiarities of individual constitutions which modify the phenomena and responsibility of the drunken state, attention is called to some fundamental traits which characterize races, tribes and fami-

lies, and which impress distinctive features upon inebriety.

The *Celt* possesses a physical organization in the highest degree sensitive. His appetites are strong, his aspirations are unbounded, his ideals are the exaggerations of fancy, and much beyond the reach of the actual. The Celt is frequently seen either in a state of radiant hope or gloomy despair. If he is an inebriate at all, he is an excessive drunkard. There is no moderation in his cups. His time is passed in getting drunk or becoming sober. His is a character of contradictions and extremes. In the Celt, the pleasures of sense are not always satisfied by their reasonable gratification. Sensuality in him often is bounded only by the limits of physical endurance.

When such a nature is addicted to the alcoholic habit, the indulgence is likely to be intemperate and destructive. The craving for intoxication is like that of dipsomania—almost irresistible. The Celt drinks the strongest liquors, and in great quantities. His will is feeble in the presence of temptation, for his passions are violent and unruly; and this is especially true with respect to intoxicating liquors. In a manner parallel with the dipsomaniac (whose will is weak from disease), the will of the Celt is weak through the constitutional organization of the race. The Celt, when an inebriate, may abstain *altogether* by a strenuous effort; but commonly, he cannot "drink in moderation."

It is a widely spread notion that, if the dipsomaniac would partake of small quantities of alcoholic liquor daily, his craving would be satisfied, and he would thus avoid his periodical spasms of intemperance. The fact is, that alcohol directly *weakens* his power of resistance by overcoming the inhibitory functions of the nervous system, and hypnotizing the moral nature. It therefore happens that the will, already feeble from disease with respect to the alcoholic temptation, is, in him, completely overcome, destroyed, when his brain is even partially affected by the alcoholic poison. The dipsomaniac may possibly, under the pressure of uncommon and superlative motives, abstain for a short time altogether; but he can never drink in moderation. The moderate drinker has moral inhibition to contend with; the total abstainer has not. Ordinarily, a single dram completely annihilates what little will or self control the dipsomaniac may have by nature, and a spell of drunkenness goes right on, till the physical organism is poisoned and exhausted. Indeed, the interference of the superlative motive, with the course of the dipsomaniac, is more of the nature of a brief substitution of some antagonistic *emotion*, stronger than the alcoholic crave, than it is an assertion of true will power. The intervening emotion may arise from grief, or overwhelming disaster. But, in

the nature of things, it must be temporary; and when it passes away, the neurotic tendency is resumed.

It may, likewise, be possible for the Celtic inebriate to abstain totally from alcoholic indulgence; but it is usually impossible to partially abstain. To him, temperance in the sense of limited drinking is quite out of the question.

These facts and considerations warrant the inference that the constitution of the Celtic race contains in its elements peculiarities that are not common to human nature in general, and that do materially modify the character of inebriety. Liquor-drinking among the Celts is impulsive and extravagant, and drunkenness is likely to exhibit its worst and most furious aspects. In this race, especially, may be engendered homicidal inebriety, maniacal inebriety, *trance inebriety*, to say nothing of the unbidden impulses to all manner of inebriate vice and crime; and all this, not from the stress of actual *disease*, either personal or through heredity, but from the natural and necessary influence which the peculiar constitution of the race exerts upon the phenomena of alcoholic drunkenness.

5. There is considerable difference, not to say contrast, between the constitutional peculiarities of the *German* and the Celtic races; and the modifications impressed upon the phenomena of inebriety by the distinctive traits of the German character are as singular and interesting as are those associated with the Celtic constitution.

Phlegmatic is the usual term employed to designate the German temperament. The German of to day is essentially the same as the German described by Tacitus. He is the unswerving and unchangeable *democrat* of history. He will possibly agree to surrender a part of his individuality into the keeping of society at large, in order to secure certain social and civil advantages—notably, protection and security; yet, should he be exposed to inconvenience on that account, he is ready to repudiate at once the compact. Touch him on what he deems to be his individual privileges—as, for instance, in the matter of temperance legislation—and he will deny the right of society to control him. He loudly inveighs against the curtailment of his “personal liberty,” and he will claim for him self the utmost individual license, rather than willingly submit to what he regards as slavery.

The Celt apologizes when he gets drunk. He explains that he has trouble to contend with, or disappointment, or sickness, or death; and he professes that he drinks to soothe an insupportable anguish of spirit. But the German never deigns to give a reason for intemperance. He declares that he has a right to get drunk, and, indeed, that drinking, so far from being harmful, is positively beneficial, and he verifies his opinions on the subject by bringing beer into his

family to be used by all its members. The German does not crave the strong and overmastering liquors that are so alluring to the Celtic nature. He seldom becomes helplessly intoxicated; but, unlike the Celt, he drinks with steadiness and regularity, and is not liable to be disabled with the deep prostration of inebriate excess.

Unquestionably, the beer of the modern German is the drink described by historians as the national beverage of the wandering tribes of that people in the days of Julius Cæsar. It is a drink containing considerable alcohol, yet so tempered with other ingredients that it sustains its inebriating influence steadily, and with little liability to sudden abatement. When the German arrives at the point of inebriation where the song and the muddy witticism break forth, he has little difficulty in maintaining his condition for a considerable length of time. Not so the Celt, who prefers the stronger drinks of whisky or brandy. His nervous exaltation is so glorious, so ecstatic, that he becomes intent on elevating his feelings and fancies, if possible, still higher, and the potations are redoubled, soon ending in mental disintegration, stupor and oblivion.

The desire for alcoholic indulgence in the German race is, therefore, influenced by the physical constitution of that race. The German calls for a peculiar and modified inebriety, and the ingenuity of his mind has discovered and prepared a material which exactly fulfills his wishes in the matter of inebriating drinks.

There is, perhaps, small encouragement in attempting to influence the German inebriate in the direction of abstinence. His inebriety belongs to his constitutional nature; it is *sui generis*. It is, in fact, a leading characteristic of his race, and has been recognized as such from the time of his first appearance in history. No amount of evidence seems to be competent to shake the faith of the German in the harmless properties and useful virtues of his national beverage. Beer is German, naturally and constitutionally, just as the instinct of personal liberty is German.

In an ancient period of time, the German people inhabited wild and inhospitable woods and morasses. Their houses were poor and open huts, set up without labor, and abandoned without regret. They were ever ready to shift their habitations and country for others that were more inviting. But, above all, for our present purpose, they drank habitually and copiously a kind of intoxicating liquor, “corrupted,” as Tacitus has it, into a “semblance of wine.” An important point is, these people have amended their houses, but not their drinking peculiarities.

The Scandinavians, a neighboring people, not only partook of this same alcoholic drink as long as they lived, but they believed that they would be “served with horns of mead and ale” after

death, in *Valkalla*, the hall of Odin—the paradise of heroes.

In Saxon England, the characteristic national revels were embalmed in song, for

“ ‘Tis merry in hall
When beards wag all ”—

a description totally inapplicable to the frantic and insane fury of Celtic intoxication.

The application of some of the principles advanced in this paper is of much wider extent than a superficial consideration of them would indicate. I will confine myself, however, to a single point.

Prof. Wiesmann, of Friburg, has recently claimed that “characters *acquired* by the parent are not transmitted to the offspring.”¹ There is nothing to show that the national habit of beer-drinking might not have been in entire accord with the barbarous customs and surroundings of the ancient German people. It is not impossible, indeed, but the habit may have been, under the circumstances, conservative and beneficial. But as the manners of the ruder times became softened, and good houses and pleasant homes arose on all sides, while the lights of civilization began also to glow and brighten, the ancient custom of drinking was not correspondingly affected. It was not abated, apparently, in the smallest degree. What was at first, probably, a habit merely *circumstantial*, became, by long continuance through ages, a habit *personal, central, constitutional*; and, when the ancient circumstances had disappeared, the hereditary mark, affixed to the constitution of the race, remained unmoved and unchanged. So deeply implanted is the proclivity for malt liquors in the German people, that it is questionable if a portion of the advantages and pleasures of civilization itself would not be surrendered, rather than the national and traditional habit of beer-drinking should be abandoned.

Illustrations of the influence of race on the characteristics of inebriety might be multiplied. The American race, the African race, and many distinctive tribes and families, furnish examples of the fact that the phenomena and responsibilities of drunkenness are modified by constitutional peculiarities. And this truth shows that in estimating the motive and guilt of imputed crime, the utmost circumspection, discrimination and industry should be brought to bear on the investigation. For it shows a weakness in the legal assumption that the criminal inebriate knows, before he drinks, what will be the effect of drunkenness upon the powers of his mind and will.

TREATMENT OF THE OPIUM NEUROSIS.

Read before the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY STEPHEN LETT, M.D.,

MEDICAL SUPERINTENDENT OF THE HOMEWOOD RETREAT, GUELPH, ONT., CANADA.

It is not my intention to enter into elaborate statistics to prove the prevalence of the opium disease, or to discuss the causes which operate in its production; suffice it to say, that the habitual consumption of opium and its products does exist to a very alarming extent in this country, and that some of the causes which give rise to this malady are under our control; others are beyond our power. Nor do I purpose portraying the dire physical and mental manifestations resulting from the daily and prolonged use of the drug, interesting and instructive as the subject might prove to be, but rather do I wish to confine myself to a consideration of the treatment of this disease as it is presented to us, and indicate those methods which, in my hands, have proved most practicable, and, in my opinion, calculated to produce the best results.

In that plan of treatment which I am about to advocate, I cannot lay claim to originality, having closely followed the lines marked out by others in the plan of treatment known as “gradual reduction.”

In attempting to treat the opium disease, it is all important the physician should eliminate from the mind the *vice* theory, and consider the case in the light of a *disease*, which presents certain pathological conditions requiring skill, patience and sympathy to successfully combat, fully as much as when he is treating other forms of disease.

What the special pathology of this disease is has not been clearly demonstrated; but that such a condition exists can hardly be questioned, and has been strongly insisted upon by eminent authority.

When we find a patient able to take repeated poisonous doses of such a drug as opium, with perfect impunity, and when it is demonstrated that such doses are essential to his bodily comfort, or even necessary to sustain life itself, certainly there is the justifiable inference that some change in the animal economy has taken place, that a departure from normal action is set up, and that a pathological condition is established. Dr. Clouston, in the July, 1890, number of the *Quarterly Journal of Inebriety*, clearly recognizes this diseased condition, while Dr. Charles L. Hughes, of St. Louis, in the *Alienist and Neurologist* for July, 1886, makes mention of it in the following language: “The long continued use of opium or of its salts engenders a disorder of the nervous system which is entitled to distinct recognition. Its sequence is as much a pathological entity as alcoholism, saturnism, hysteria or chorea.”

¹ Journal of Am. Med. Ass'n, 1890, Dec. 27, page 924.

"Meco-neuro-pathy," he says, "is as much entitled to recognition as that well-known disease, epilepsy."

This assertion he fortifies by many interesting and undisputable facts, and in this connection, draws particular attention to, and points a vividly realistic picture of, the dire results consequent upon the sudden deprivation of the accustomed drug in an opium habituate. Many other eminent men hold the same opinion, and I look forward to no distant date when we shall see these assertions verified by microscopic demonstration.

These pathological changes appear to be situated, chiefly, in the nervous system, more particularly in the great nerve centers, and thus false impressions are conveyed to all organs of the body, thereby interfering with the due performance of their several physiological functions, producing disturbance and discord where harmony and normal action should exist.

Without enquiring further into the pathology of chronic opium poisoning, and accepting as fact that disease does exist, it remains for me to give a résumé of the methods of treatment advocated and adopted.

In the first place, we must bear in mind that there is no drug known to the medical profession which will cure this disease. We have no *specific* for it. Substitutes there may be, but substitution is not curing the neurosis, and the risk of producing a worse disease thereby requires extreme caution as to the selection of such a remedy.

Three separate and distinct modes of treating the opium habit are advocated and practiced: 1. That of abrupt and total withdrawal of the drug; 2, its rapid reduction; 3, that of gradual reduction.

As regards the abrupt withdrawal of the drug, I cannot for a moment countenance such a barbarous, inhuman and dangerous procedure, involving, as it does, the most exquisite torture, which no being on earth can fully realize save the opium habituate deprived of his opium. The shock to the nervous system is so intense as to make a lasting impression, which is manifested in the higher brain functions, and the risk of fatal collapse is unjustifiable. Words fail me to adequately express the reprehension I would cast upon those who set out on this despotic course, or to convey to you an appreciable idea of the misery and suffering it entails upon a most pitiable and helpless creature. I am astonished beyond measure to find so eminent an authority as Dr. Clouston, of the Royal Edinburgh Asylum, advocating and carrying this treatment into practice. The deservedly recognized marked attainments he possesses, the careful and sound observations he has made and recorded in other neuropathic disorders, the valuable work on in-

sanity he has published — a book which should adorn the library of every asylum physician — and the distinguished position he occupies among his confrères, gives weight as coming *ex cathedra* to anything emanating from his pen. I would not dare to thus criticise his treatment of the morphinomaniac were it not that I feel it a duty to humanity to protest against such cruelties being practiced upon a most unfortunate class of sufferers who are powerless to defend themselves. How a man endowed with the keen accurate perception and high educational attainments of Dr. Clouston, whose long and varied experience among the mentally afflicted must have developed in a marked degree that sympathy for suffering humanity which is so essential to the successful treatment of the insane, could ever advocate, much less carry into practice, such "heroic" treatment, is to me, at least, a problem incapable of solution.

In his article published in the *Quarterly Journal of Inebriety*, vol. xii, No. iv, page 311, he clearly recognizes the diseased condition we are now considering, and truly describes in terse language the subject thereof in the following words: "A morphinomaniac, in the advanced stage of his complaint, is a most miserable object in mind and body. He is manifestly diseased in all his nerves and most of his other functions. There is just one other being on earth who is more miserable-looking and more miserable, and that is the morphinomaniac who is being cured by enforced abstinence. The one is alive; the other is more than half dead. As we shall see, the fight is not altogether for the cure of the deadly habit, but in the first instance, to enable the patient to live through the cure."

Such are Dr. Clouston's accurate observations; nevertheless, in the very next paragraph he gives us a sample of his mode of curing this disease by *enforced abstinence*, which he justly admits causes a fight to keep the patient alive. Look at the pitiable subject he practices this on. A man, in the first instance, weighted down with a "distinct nervous diathesis," who at an early age suffered under a severe illness, which left him weak and sleepless. He "crams" beyond his strength to pass examination at college; buoys himself up on opium; he becomes the subject of rheumatic arthritis at the end of twenty-five years of morphia disease; under compulsion, he places himself as a voluntary patient in an asylum. He now presents the appearance of a "broken-down looking man," a physical and mental wreck. He was treated with beef-tea and brandy. We are told "the beef-tea caused diarrhœa, and had to be stopped. He could retain milk, liquid custards and brandy better than anything else. The heart's action got very weak, and digitalis seemed to strengthen it. *No morphia was given.* For a week he was horribly depressed and debil-

itated, and his life was certainly in danger." Under chloral and bromides, "he slept restlessly and awoke with a feeling of horrors." Contrary to what I would have expected, he weathered the storm and reached anchorage, but what a wreck, to use Dr. Clouston's own words! "His brain is irretrievably damaged in all its higher functions by his twenty-five years' continuous intoxication by opium."

How sublimely does the doctor take shelter behind this twenty-five years of so-called "intoxication by opium," and ascribe to this cause all the permanent damage done to the "higher brain functions." Granted that the opium was an important factor in the production of this dire result, did not the fearful ordeal the unfortunate victim went through tend to still further disorganize and produce a marked untoward impression upon an already mentally depressed and physically diseased condition; could the same man, crippled as he was with an originally unstable nervous organization, even though he had never tasted an opiate, have gone through a similar ordeal and retained a "*mens sana in corpore sano*;" would not a milder form of treatment have at least prevented so terrible a shock and given nature a far better chance to repair the inroads made upon the patient's health by the long continued morphia habit? What was there in the result that in the smallest measure compensated for the terrible suffering sustained in effecting a so-called cure. What advantage accrued either to the patient, society or science, by this barbarous treatment? Would it not have been better to have permitted the poor creature to continue his morphia, and in his own way enjoyed what few years were left to him to live, and when death was inevitable have quietly, gently and tenderly lowered him to his grave with as little pain as possible?

Two other cases are recorded by Dr. Clouston in the same article; the same line of treatment was adopted, the same ordeal passed through, similar results obtained. If this is success, if this is a cure, "I will none of it." I have said enough about the abrupt withdrawal plan of treatment. Let us draw a curtain over this horrible picture, hide it from view, and pass from so revolting a topic to the second plan of treatment, that of

RAPID REDUCTION.

I regret being unable to speak from experience as to the merits or demerits of the rapid withdrawal plan of treating the opium habituate. Such has not been my practice, therefore what I may say regarding it is gleaned from the literature pertaining thereto, more especially the publications of my friend Dr. Mattison, of Brooklyn, and those of Professor Ball, of the Paris Faculty

of Medicine. Both these gentlemen, as well as many others, appear to have met with marked success and satisfactory results. Certainly this method of treatment seems to carry with it many advantages. The time occupied in removing the drug from the circulation is comparatively short, from eight days or less to two or three weeks, yet it is withdrawn by such gradations that the shock to the nervous system is not so great or the danger of collapse so imminent as when the patient is at once deprived of all opiates; at the same time other remedies are employed which appear to have the desirable effect of quieting the nervous system and sustaining the patient whilst the final withdrawal is being accomplished, thereby safely carrying him through a crisis otherwise critical; when this object is attained the special remedies employed are apparently discontinued without inconvenience. Amongst such agents so employed may be enumerated, general and special stimulants, cardiac tonics and nerve sedatives, such as ether, alcohol, nitro-glycerine, sulphate of spartein, the various preparations of valerian, jamaica, dogwood, cannabis indica, belladonna, hyoscine, electricity, hydrocyanic acid, phosphoric acid, paraldehyde, chloral and the bromides, especially the bromides of soda in large doses mounting up to $\bar{3}$ i per day. This latter has been especially brought to the notice of the profession by Dr. Mattison, in whose hands it appears to have proved a valuable remedy, fulfilling a most important office and safely meeting all required indications. As accessories, hot mustard, salt or electric baths, sustaining nourishment, careful nursing, and the best of hygienic surroundings.

As already stated, I have not followed out the treatment by rapid reduction, chiefly because I have found the more gradual method, though involving more time, eminently satisfactory and have thereby safely and successfully cured many patients whose enfeebled condition appeared to me to prohibit the more rapid method. I must also confess being somewhat skeptical as to the ease and freedom from pain with which an opium habituate can be cured by rapid reduction, and before abandoning that mode which I have found satisfactory, I would like more information than I possess as to pain, discomfiture, restlessness and general relaxation of the mucous membranes. Whether in the rapid reduction plan such phenomena are severe or merely trivial in character. Again, it appears to me that the time required to restore the general health and overcome the inroads made upon it by years of opium addiction, is quite equal to the extra time involved by the gradual reduction method. Many writers state that fully six months should be occupied in such restoration, but I know in practice, the rule is a much shorter period spent under special medical supervision.

GRADUAL REDUCTION.

It now remains for me to consider the third mode of treatment, viz.: that of gradual reduction, which has been so ably described and advocated by Dr. Hughes, of St. Louis, and practiced by myself and many others. It is claimed to be rational, humane and a safe line of treatment, reassuring to the patient, and what is all-important, presents to their minds a feasible and comparatively easy mode of casting off these shackles which have so unrelentingly bound them for so many years, constituting them veritable slaves to an overpowering drug which is gradually but surely pressing them onward to meet a miserable and appalling death, which comes at last as a relief to a more pitiful and painful existence.

This treatment essentially consists in a slow, even and methodical withdrawal of the drug, without substitution; at the same time using all the means known to medical science to restore, as far as possible, the shattered nervous system, which is the universal condition of all these cases. The gradual withdrawal of the opiate is effected by decreasing the amount in fractions of a grain at each dose, and the following is a general outline of my mode of procedure.

Having by a categorical enquiry ascertained as nearly as possible, the amount of opiate the patient is in the habit of taking during twenty-four hours, I calculate its equivalent of morphia, then dividing this amount by the number of times it is necessary for him to resort to it during the day, a fair approximate of a simple dose is arrived at. This dose is carefully weighed, administered, and its effects noted; especially as to the following points: Does it sufficiently sustain the patient and keep him comfortable? How long does its effect last? When would a repetition of it be necessary to prevent depression, and would a smaller dose suffice. In a few days by careful observations of this nature, accuracy is obtained, a basis of treatment instituted, and reduction commenced. The rate at which reduction progresses must be governed entirely by the nature of the case in hand. Some patients will bear to be reduced faster than others; much depends upon the physical condition and the quantity of opiate consumed, those taking large quantities can, at the commencement, be reduced faster than where a less amount is the starting point. The guiding rule is, to remember there is a point at which the patient remains comfortable for a certain number of hours. That point can be noted between the extremes of stimulation by excessive opiate and depression consequent upon too small a dose. Upon the accuracy of adjustment of the dose to this point, depends the ease or the discomfiture of the patient, and success in treatment. The rate of reduction also

varies with the progress of the case. As a rule, when treatment is commenced with a patient taking, say 20 grains of morphia a day, reduction can be effected at the rate of about one grain every three days. As the quantity taken in twenty-four hours gets less, so also must reduction be more gradual, so that it will require four, five, six or even ten days to withdraw a single grain. When a point is reached at which only one grain is consumed in twenty-four hours the greatest skill, care, and caution is necessary, and to remove this single grain I usually employ from three to four weeks, gradually paring a fraction of a grain from each dose, and when you remember that that last grain is divided into perhaps three or four doses in the day, the final dose being brought down to so fine a point as $\frac{1}{1000}$ of a grain, you can appreciate the delicate and gentle manner in which it is withdrawn. No appreciable difference in the dose is noticed by the patient, no shock is produced on the nervous system, the dreaded upsetting of the stomach is avoided; there is little or no relaxation of the mucous membranes, diarrhoea is almost absent, or if present is so mild that the patient will not complain of it. There is no restiveness or inability to continue at a fixed occupation; sleep is usually good, natural and refreshing, and the patient finally slips from under the yoke of the demon opium without being able to note when he took the last dose. Emerging from his years of tyrannical bondage with a new lease of life, buoyant in spirits, physically improved and mentally bright.

Such a course of treatment necessarily involves constant and ever watchful care on the part of the medical attendant, and such physicians who are not prepared to devote time and patience to it had better not set out in the task. To those who follow it out faithfully, the result will amply reward them for all the trouble involved. Each dose should be put up by the physician himself. Accuracy in measurement is essential, none the less so, is punctuality in the time of administration; this cannot be accomplished without some fixed method to work upon. With such method the task is not so insuperable as might at first appear, though I doubt if the general practitioner could carry it out; the uncertainty of his movements would seriously conflict. In order to insure accuracy of dose and steady reduction the method adopted is as follows: When regular treatment is commenced two mixtures are compounded and the bottles labelled respectively 1 and 2. No. 1 is a mixture containing some of the vegetable tonics, with glycerine and water sufficient to form a 5200 mixture; to this is added one-half the amount of morphia per 5i you wish to give at a dose. No. 2 is precisely the same as No. 1 minus the morphia; 5ii are now taken from No. 1 and admin-

istered to the patient, the same amount is taken from No. 2 and poured into No. 1. The latter will now contain a fraction less morphia per $\bar{5}$ i than the original mixture, that fraction multiplied by 2 represents the amount of reduction at the next dose. A record of each dose should be accurately kept; it is most important to be able to tell at any moment what the morphia strength of the solution is, as there are times when it is necessary to discontinue the reduction for a few days, or other periods when it is prudent to increase the rate of reduction by removing a certain amount of the mixture from the bottle, or an accident may arise whereby the bottle gets broken or some of the mixture spilt, etc.; under such contingencies, unless the strength of the mixture is absolutely known, it cannot be replenished without interfering with the even tenor of treatment. It is also desirable to know the rate at which reduction is proceeding, and when nearing the end, to be in a position to say that such a dose will be the final one, and be certain a crisis will not follow its withdrawal.

Such a record as I have indicated is easily kept in a case book with suitable rulings for the following headings: Date, time for dose, bulk of mixture, amount of morphia to $\bar{5}$ i, quantity of morphia at each dose, daily amount of morphia, daily reduction, quantity of morphia left in mixture. It is but a minute's simple calculation to place the correct figures in the appropriate columns, and a glance at any time gives you accurate information. The calculations are best worked out in decimals and should be carried to the third decimal place.

Thus I have given you a general detail of the method I adopt, to evenly and methodically reduce the morphia. Certain modifications are necessary to meet special exigencies. Should reduction be going on too rapidly and signs of depression set up, the patient is easily righted by halting for a few days and holding him at the point reached. It is sometimes astonishing to see how rapidly the system will respond to this rest; in a short time the patient will be bright and buoyant, when, the mixture being replenished, reduction may again be safely resumed, though perhaps at a slackened pace. In some cases many such rests are required. In others reduction may proceed steadily from commencement to finish without inconvenience.

Concurrent with this reducing process our skill must be directed to restoring the physical health and bringing it as nearly as may be to a natural standard. Sustaining nourishment, if necessary repeated at short intervals, frequently a light meal at bed time, is of great advantage. But usually the appetite soon improves and regular meals are enjoyed. Pleasant recreations of a light nature short of fatigue, and out of door exercise should be encouraged. Tonics, chiefly iron

and quinine in tonic doses; the syrups of the hypophosphites is an admirable form. Some cases, however, do not bear the strychnine well; when it is tolerated it proves useful. In emaciated cases cod-liver oil emulsion will be found of service.

If from causes you cannot control, time is an important consideration and you are obliged to push the reduction more rapidly than sound judgment would dictate, restlessness and loss of sleep coming on, gr. $\frac{1}{2}$ doses cannabis indica ext., will prove a valuable aid. Hot salt baths with friction to the skin is of much value; $\bar{5}$ ss. doses fluid ext. humuli often produces refreshing sleep, or occasional doses of chloral, paraldehyde or antipyrine at bed time, will be followed by good results. Electricity and stimulating liniments will allay the pains sure to arise if too rapid reduction is practiced. Salsiminum will relieve old neuralgias now likely to give trouble.

All opium patients are more or less troubled with constipation, oftentimes very obstinate. Keep the bowels regulated but do not make a "Balaklava charge" on the alimentary canal by giving drastic purgatives; paralyzed nerves resent such treatment. "Milder measures best prevail." A copious enema will relieve the lower bowel, and lubricate the passage for the discharge of hardened accumulations. A mild mercurial is often of much service. When it is desirable simply to clear the intestinal tract my sheet anchor is fl. ext. cascara sagrada and glycerine in equal parts.

Alcohol in any form I disapprove of, it invariably causes a demand for more morphia. Bromide of potash in sufficient doses to be of any use causes too much after-depression. Cocaine in the treatment of the opium habit I have tried and discarded as dangerous in the extreme.

In cases of double addiction of morphia and alcohol, or morphia and cocaine, I invariably at once withdraw the alcohol or cocaine and continue the morphia, giving sufficiently large doses to keep the patient comfortable. I can fight and conquer one devil but not two.

Whatever form of opiate is used, I follow Dr. Hubbard's recommendation to discard it at once and give its equivalent of morphia. So also with the use of the hypodermic syringe; I abandon that and administer morphia by the mouth. Patients are apt to object to this at first, but they soon realize the many advantages gained by the change. The same dose administered by the mouth will sustain the patient fully as well as when given hypodermically; it is however, less prompt in its action, but more lasting.

With very much broken down and highly nervous patients, I permit them to retain their syringe and morphia until they become accustomed to their surroundings and the new order of affairs; it is a source of much comfort to them, dispels

their fears and in my experience will not be used unless necessity requires it. In a few days, when confidence is established, the syringe together with all morphia, will be voluntarily handed to me, and the patient will place himself entirely and unreservedly under my care, willing to assist in the treatment of his case to the utmost of his ability.

Lastly, I would enjoin you to pour out your full sympathy towards the unfortunate opium habituate who has had a hard battle to sum up enough courage to present himself to you for treatment. He needs help. He needs care. He needs kindness. He has suffered long years of torture and deprivation; been tossed hither and thither, like a rudderless vessel, upon the turbulent waves of a cold and austere world; looked upon as a vicious outcast whose every action is treated with suspicion, his statements doubted, his case mismanaged. Give credence to what he tells you. Extend a rescuing hand to the drowning man. Pour oil and wine on his smarting wounds, let your full sympathy and aid go out towards him; you will then brighten a dark spot in the deepest of despair, and have the heartfelt thankfulness of an ever grateful fellow being.

DOES SCIENCE JUSTIFY THE USE OF ALCOHOL IN THERAPEUTICS? IF SO, WHERE? WHEN?

Read before the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, Washington, D. C., May 6, 1891.

BY ELISHA CHENERY, M.D.,
OF BOSTON, MASS.

The time is upon the profession to review and recast its notions concerning the use of the alcoholic compounds in the treatment of disease, grounded upon what they are, what they do, and what they do not do; for Argus-eyed science of our day shows alcohol to be widely different from what was supposed of it, in the years that are past. If our fathers drove their cows around a stump to make them give down the milk, we are not bound to do the same. Moreover, the liquor treatment has come to have a moral bearing, which both the human and the divine of our profession requires that we respect. And let me here add what the learned President of this Section has said: "The influence and teaching of the medical profession on the great drink question, is most imperatively demanded." Yet I radically differ from him in another statement: "Medically and scientifically, the whole subject is the polar region of mystery."

Certainly this speaks poorly of the candor of those who still prescribe it. If so, then why not leave it alone?

Bunyan got his hero into the Slough of Despond; but does any one in his senses believe that

the Slough of Despond is a necessary part of the pilgrim's pathway?

My subject compares to my time, to-day, like a man's hat to a boy's head. Hence I can touch only a few points, and that in the most unsatisfactory way—of leaving out most of the proofs of my positions.

ALCOHOL AS A RESTORATIVE.

This term includes the tonics—agents which increase strength and overcome languor—the promoters of the constructive metamorphoses, and the force producers. It excludes that which adds nothing, only whips out the strength the body already has. Restoratives are in great demand. The physician to-day prescribes them more frequently than any, if not all, others. He feels, when doing so, he is adding to the sum total of vitality.

Considering alcohol in this relation, we meet the fact that its chemistry is squarely against it. Not a particle is incorporated into the bodily tissues; so, to say the least, he is visionary in the extreme who prescribes it with the idea that it is incorporated, or that it incorporates anything else.

It contains carbon, as all carbo-hydrate food substances do; but that carbon cannot be extracted from it as from them. They all undergo certain changes, as chemistry shows; while it enters, pervades, and escapes from the body as alcohol, no proof of its transformation, either in the digestive tract, the blood or the tissues, ever having been found. This one fact of its indigestibility nullifies all arguments in its behalf as a force producer. If any contend that it does change, let them give the evidence.

The various symptoms, commonly attributed to this supposed change, are very satisfactorily accounted for from its known irritating and anæsthetic actions. Yet if we admitted all that has been claimed for it in this respect, we concede very little, for Voit and Subbotin say: "In the amount we can take without injury, its importance as a nutriment is too small to be considered." But we have no warrant for the concession.

That all the liquor taken cannot be recovered, we allow. It is the same when alcohol is mingled directly with freshly drawn blood: But the mere loss of a portion is not a proof that that portion changes and becomes useful. Such conclusion is not scientific nor rational. The loss of my knife is not proof that Jones has it, or that he stole it. As well contend that Stanley's "rear column" found Emin Bey. Better do as Hahnemann did—jump from the tangle of medicines into their spirituality. Right reason requires that we withhold our conclusions till we establish the premises. In the light of the foregoing, how unreasonable were the assumptions

of Dr Todd: "Alcohol is the most easily digestible and assimilable of substances. . . . It oxidizes in place of the tissues." Equally absurd is the theory that alcohol conserves tissue, as we showed in our essay last year.¹

That it is sustaining because some persons have lived a long time while taking it, is not conclusive. There is every reason to believe they would have done better without it. Had Dr. Tanner and the others who fasted longer than he, depended on alcohol rather than on the store of nourishment in their bodies with water to dissolve it, it is unquestionable that the undertaker would have had them long ere the forty or forty-five days expired. But, so far from acting as a restorative, abundant, careful observation shows that liquor actually depreciates the strength one has. It is the strong, not the weak, who bear it—not the young, the feeble, and those addicted to it. In other words, the strong can *resist* it, while the weak cannot.

Thus speaks Dr. Chambers: "Above all, I would caution against employing wine as a substitute for the true restorative treatment." "To call alcohol food," writes the Editor of the *British Medical Journal*, "in the present state of our knowledge, is an abuse of language." "The popular belief," says Dr. A. Mullan, "that beer and other alcoholic drinks are strengthening, is a mistake, a delusion, a mere superstition, which receives no support from science."

ALCOHOL AS A STIMULANT.

This class adds little or nothing to the bodily forces. They call out what was in store, using it up before its time. They act promptly, and for the time only. Their repetition is a matter of much discretion. They take from the sum total of vitality, and lead to exhaustion unless wisely guarded. Alcohol has so monopolized this term, that alcoholics and stimulants are at present quite synonymous. But is not the term mostly misapplied when applied to alcohol? When and where does it summon out the forces of the body the better to resist opposing forces? Never, except in very small doses, much smaller than we should be likely to give, if we give it with the idea that it is stimulating.

If we, for a moment, lay aside our pack of vague notions, and sit down at the deliverance of instruments of precision, we shall learn for certainty that any considerable doses do not stimulate, but depress and weaken. "Careful observations," Brinton states, "leave little doubt that a moderate dose of beer or wine will, in most cases, diminish the maximum weight a person can lift." So Liebig: "The circulation will appear accelerated at the expense of the force

available for voluntary motion, but without the production of a greater amount of mechanical force. It is attended with an inward loss of power." Prof. Marvaud of France, Zimmerberg of Germany, Richardson of England, and Martin of Baltimore, have wrought at this and find alike. According to Prof. Martin, as much as an ounce of whisky or brandy always lessens the force of the heart, though generally increasing its frequency. Prof. W. E. Ground, of Toledo, asserts "that it acts as a paralyzer from the first, through paralytic effect on the nerve centres, as in experiments where the inhibitory nerve is cut." Alcohol adds no heat. It strengthens neither body or mind; and this is not only science, but the common sense view of common experience. Alcohol agitates the system, while nutritive agents perform their work silently within, leaving other functions undisturbed. Moreover, it has certain drawbacks which stand in the way of its repetition, which proper stimulants do not have. Cold, or mechanical irritation to the stomach, increases heart frequency, and heart and vascular force. For the instant, small doses of spirits will do this, but, directly after, the absorbed portion begins to paralyze the nerves and capillaries. Hence heat, hot drinks, the aromatics, etc., are the proper means to warm a chilled person. They do not tumble the blood into the external capillaries as alcohol does, to the neglect of the more important internal parts. Whales are made to resist cold and not heat. Their exterior is in contact with the waters of the polar seas, while under their skins is a thick layer of non-conducting blubber, beneath which their warm blood circulates. Our bodies are made to resist both heat and cold. Exposed to the latter, perspiration stops, the skin contracts, forcing most of the blood beneath the subcutaneous layer of fat, where its heat is protected. A drink of grog unlocks the skin and drives the blood to the surface, dissipating its heat, just as would happen to the whale if his blood were brought to the outside of his blubber, when it would lose temperature and his heart chill. Not only is alcohol bad in this way, but it does more; it puts a wet blanket over the internal fires, by shrinking and depressing the functions of the blood cells. So, so far from its being a stimulant to bring out the forces of the system to resist cold, it is a traitor, and appears doubly armed on the side of the enemy. Arnold had his good qualities; so has this. If a person has been exposed to severe cold, and is suffering internal pains and cramps from the vascular engorgement, no doubt alcohol has temporary helpful relations to the case, bringing the blood away to the surface. So has it useful relations to syncope, to shock, and to other cases of deficient brain circulation, where its irritation to the stomach, and not its absorption, may serve. Hence,

¹ "Does Alcohol Conserve Tissue?" in pamphlet. Free to physicians who send to the author for it. See this much more fully shown in the author's "Alcohol Inside Out," 12mo, 350 pages, mailed for 5¢.

what is used for the purpose should be strong. There are many other things as good, if not better. Thus the horizontal position, splashing the face and neck with cold water, cold or hot drinks, aromatic teas, camphor, ammonia, are appropriate, and are the people's remedies; while physicians may add amyl-nitrate, nitro-glycerine, and other things too numerous to mention. For years, nitro-glycerine has been the chief remedy of the writer. It is good to administer in anticipation of faintness from operations. So iron, and not alcohol, for anæmia and anæmic neuralgia; bismuth for gastralgia and pyrosis; not whisky, but the bromides, capsicum, digitalis, feeding, nutritious enemata, for delirium tremens; heat to the chest, camphor, ammonia, strophanthus, digitalis for the flagging heart; not alcohol, but digitalis, strychnia for dropsy; camphor, chloroform, turpentine, not liquor, for malarial chills; not liquor, but turpentine, ergot, salt, milk, for hæmorrhages; not alcohol in congestive dysmenorrhœa, inflammatory colic, dysentery, and a thousand other conditions in which stimulation is required. [In all cases of nervous exhaustion, or where the stomach is at fault, Dr. Archibald Billings says "restoration will not be expedited by stimulants," meaning alcoholics. Being, then, rather a hindrance than a help, good sense is on the side of the surgeons of certain corporations where accidents are common, in recommending that the employes be prohibited from resorting to liquor in cases of injury.]

ALCOHOL AS AN ANÆSTHETIC.

It would be well if this term, as applied to alcohol, were excluded from medicine. That alcohol by the skin, stomach, lungs, obtunds the nerves, paralyzes the muscles, stupefies the brain, needs no confirmation here. As persons see these effects, they name it according to their conceptions—intoxicant, narcotic, paralyzant, etc. I use the word anæsthetic, for, like Aaron's rod, it swallows up all the rest.

Anæsthesia is the most conspicuous of its effects. It is this which balms the feelings and brings the cheer; that smothers the aches and the pains; that exhilarates the mind, beguiles to repetition, to increasing doses, to habit, to inebriety, upsetting the mind, and raising the devil.

Alcohol is thus the very mad dog of *materia medica*. Nevertheless, it was the best anæsthetic known to our fathers. They also wore wooden shoes, things we need not wear. Ether, gas, chloroform, and many other agents have come to the fore, pushing it to the rear. They are not so deceptive, so seductive, so habit-producing, and those who handle them are not so likely to catch the Tartar—inebriety.

Having so numerous and efficient agents as substitutes, agents which have not its peculiar

back-cut upon the blood cells, I need not waste time in pointing out when and where it can be used in this direction; for it was the new cane the old man used while all the former ones were put in a brace in the wood shed. Neither need I stop to indicate the purposes its varied properties fit it to serve as an external remedy. I therefore pass at once to my last point.

ALCOHOL AS A PERTURBATOR OF THE ORGANISM.

The effects of alcohol on structure, and so, on functions, marks it as the most remarkable disturber of the animal body with which we are acquainted. Whatever else it may do, here it takes preëminence. Its etherial influence, to be sure, are the lulling wings of the vampire; in this is its mouth applied to the vital fluids. Its anæsthesia is the dummy hand of the thief; here are the concealed fingers which filch the purse. The mental exhilaration it produces is the smiling face of Brutus; this, his bloody hand which plunges the poniard.

With all that is known of the morbid changes produced by alcohol, how little is systematically considered and applied in practice? Last year I called attention to its power over the blood corpuscles, and showed a photograph of the extreme changes it produces in their physical character, in a portion of blood taken directly from a drunken man. This was right to the point. It gave ground for explanations and deductions otherwise impossible. Knowing the physiology of these corpuscles, as the gas carriers of the body, we do not require to be beaten with a club to comprehend that such alteration in their character must amazingly effect their important functions. But this is not all. The alcohol which gets into the interior of the corpuscles, acts the part of the dog in the crib and refuses the oxygen and the carbonic acid. Thus in a double sense their functions are depressed. In the paper referred to, I explained how it was that alcohol so affected their physical character, by showing that the spirit, having a great attraction for water and little or none for the substance of animal membrane as such, by the laws governing osmotic action, compels the water to come out of the cells and mingle with it on the outside. Not only does it thus collapse the cells, but it also similarly affects all other moist structure throughout the body. Who has not seen this in mucus, in albumen, in the protoplasm of rapidly healing wounds?

What it does under the eyes on the outside of the body, it does on the inside, and the more so in proportion, as they are watery and the cell walls delicate. In this way are the tendons, the muscles, the nerves, the connective tissue and the organs affected. Is there, therefore, difficulty in comprehending why the bodies of drinking young men grow old apace? An agent that will steril-

ize the cells of a pup and prevent their evolution, thus holding his body throughout in the condition of a Chinese woman's foot, must and does pervert the structures of those who drink it. Here, then, we have the key to the alcoholic pathology—the changes so conspicuous in the bodies of old toppers, and so surprisingly numerous in the bodies of moderate drinkers suddenly cut off by other causes. This shows why we cannot cure persons made sick by alcohol while the habit is continued; why surgical cases act badly in alcoholized patients; why the healing of wounds is not expedited but hindered when liquor is given; why the white blood-cells are crippled and protoplasmic movements arrested by this agent.

Here is the key that unlocks the mystery of fatty degeneration, fatty bloating. Is it strange that such organs as the kidneys, the liver, the stomach, the brain and spinal cord, the vascular system, should undergo fibroid and cirrhotic changes by so active an agent and acting in the way that alcohol does?

Here is the explanation why the bodily temperature can never be raised by alcohol, but always lowered; and why this antipyretic action cannot be rendered serviceable in practice. Here is its philosophy in weakening brawn and brain. Every other function must be depressed when the blood-cells are strangled.

Now, I ask, what reason have we to expect good from it in the treatment of any or all diseases of the respiratory system? They obstruct oxigenation and the elimination of carbonic acid. Does not alcohol do the same? They weaken; this, more. If pneumonia blocks pulmonary circulation and æration, and by heaping excessive labor on the heart, tends to overwork it and exhaust it, determining heart failure; this, more. Strange that we should lose our heads as philosophers in the face of alcohol. Would that we return to the lancet for this grave disease, relieving the volume of blood upon which the embarrassed heart has to act, and be done with this most irrational and fatal treatment of it, ever employed. If the structural changes in the lungs of consumptives hinders oxidation and weakens the body, does not liquor do the same, albeit it diminishes the cough by times? Is our philosophy correct when we give alcohol in disintegration with defective depuration, as in fevers and the like? Does it not itself increase depuration by hindering the absorption of oxygen and the expulsion of the waste, represented by carbonic acid and urea?

Certainly if it can obstruct the waste in a well man till he stinks from head to foot, it can never purify the blood of one already foul. These questions, with scores more that might be asked, being based on solid grounds, leave me little room to answer, Where? When? Give alcohol? There is nothing in physiology more certainly scientific-

cally demonstrable than that alcohol changes the structure of the blood-cells, and, through these, the functions dependent upon them, and as their functions are vital and no hindrances to them can conduce to the restoration of the sick, the reasons for alcoholic medication are driven to the polar region of barrenness. They cut the tap-root of the popular liquor therapeutics, and no human invention can make it again bear green leaves. Alcohol, when in any degree of concentration, is opposed to ptyaline, to pepsine, to pancreatine. It is contra-indicated in bilious cases, cirrhosis of the liver, gout, Bright's disease and diabetis; the last of which it can directly produce.

But this paper is not written in ignorance of the fact that many good physicians use it. Were it not that many do, the statements herein would not be worth the making. I may be wrong; we all err. In a neighboring city an astute physician stood up in a medical meeting and deposed in favor of a certain pill, relating numerous cases where he had given it with good results. Another physician followed, showing the same pills which had been gathered from the former's patients, they passing whole, only losing their sugar coats. A prominent member of this Association had a fever case which got into the typhoid state; his kidneys being obstructed, I counselled efforts to open up the kidneys and skin and so relieve the nervous condition. The doctor was obstinate, believing in "bridging the chasm" with "the bridge that brandy makes," and gave it. His bridge was rotten. I now have a patient under my care who told me he had taken quite half a barrel of different liquors on the prescriptions of this same physician, and began to improve the moment he left the liquors off. A clergyman called on me, relating that his child had been sick with the typhoid and got to that condition where the doctor said nothing but brandy would save him, and accordingly brought a bottle of it to the house. The clergyman took it, threw it into the back yard, made a liberal portion of beef tea and gave it. Soon the sweat started, and the child fell into a sweet sleep and was better the next morning. The doctor spoke of the change and attributed it to the wonderful power of the spirit. I warned that clergyman for not deceiving his doctor, and allowing him to go away, strengthened by the success of the brandy in this case, to give it with increased confidence.

It may have been good in cases of fever, diphtheria, etc., where large doses have been given and which appeared to be beneficial. If so, I am very positive that it was owing to its power over the peculiar microbes in these diseases, sterilizing and rendering them inert; for we know that alcohol, at fifteen or twenty per cent. strength, overcomes and practically destroys most of the germs about us, even the blood-cells

themselves, as I have witnessed, producing death. And it is a most wonderful provision of nature against fatality from the drink habit, that the medulla oblongata is so much more resisting to the power of alcohol than the rest of the body, continuing its functions when all else is practically dead, keeping the heart beating and the lungs moving, fanning out the poison from the prostrated blood-cells. Were it not so, how often would the undertaker's service be required to what it now is!

I know I cannot answer all your questions, yet I trust I have said enough to show you that this subject is not all a mystery, but full of interest and instruction, if we but come out of the clouds and study it from ground principles. I came up the historic Potomac, and, though the oar, the sail, the smoking steamer, seemed to indicate that the current was devious, I am sure its steady flow is to the ocean beyond. Though I note some drift-wood held in sluggish side currents, some cross currents, whirlpools and waves, I am as satisfied that the stream of alcohol, whether taken foolishly, from habit, or on the advice of physicians, in large or in small doses, has but one general course, one end—the fathomless deep.

Comparing the results of my practice with the practice of those who use it, until something more scientific in its favor comes up, some new revelation is made, the day is far distant when I shall send another Brutus after my Cæsars.

INSANITY AS RELATED TO CIVILIZATION.

Read before the Section of Medical Jurisprudence, Washington Meeting American Medical Association, May, 1891.

BY ORPHEUS EVERTS, M.D.,

SUPERINTENDENT OF THE CINCINNATI SANITARIUM, ETC., COLLEGE HILL, OHIO.

Insanity may not be, as is so commonly and confidently asserted, "a disease of civilization"—but conditions essential to the phenomenal manifestations of insanity obtain so rarely among savages and lower animals, and so frequently among civilized people, that, in the absence of contradictory testimony, the assumption that it is so, would seem to be justified. The question then becomes pertinent and interesting: What constitutional modifications are effected by, or with, the process of civilization, whereby human beings are rendered more liable to become insane? Who shall answer?

By common consent the medical profession is looked to for intelligent answers to all questions pertaining to insanity, and the insane. Is the profession qualified to so answer?

Qualified or not, there are members of the profession ever ready to respond; the least qualified, often, being the readiest. Capability to talk volubly, or write voluminously, about insanity

—or any other subject, for that matter—with an affectation of learning, is a "gift" not unknown to the profession, however reputable it may be, as a body, for its thoughtfulness and reticence. Such 'gifted' members are, as a rule, however, not the most trustworthy, as expounders of principles, or historians of facts.

By interrogating less pretentious, but ordinarily intelligent members of the profession, respecting the relation of insanity to civilization, it will be found that various opinions are entertained by them on the subject; each having some value when properly estimated; but based upon foundations of facts too narrow and incongruous to stand the test of rational criticism.

Nor should it be anticipated of such men, whose preliminary studies, and subsequent habits of thought and observation have been in the way of specializations, rather than generalizations, should grasp the question as propounded, comprehensively; or respond to it otherwise than by some more or less dogmatic assertion of personal opinion; citing this, that or the other disease, habit, accident, or incident, of civilization, as the true cause of insanity; overlooking the fact that certain physical conditions, not common to the race, but essential to the manifestation of the phenomena of insanity, must have obtained, individually, before such "causes" could become operative; regardless of all other circumstances.

The first man, for example, will assert, as an indisputable proposition, that alcoholic intemperance is the cause, direct or indirect, of all manifestations of insanity!

"The demon alcohol" as this man sees it, has superseded all old fashioned "demons" of whatever genus, or species, to whose machinations all diseases, and death itself (when not inflicted by a supremely good spirit), were attributed by our, not very remote, ancestors; and should now be held responsible, in their stead, for all the misery of mankind.

Nor is this man alone in his belief. A good man, and true, within his own bounds—devoting all the energies of being to an ameliorating of the more painful conditions of his fellow-men—his notions are not singular; nor is his conduct peculiar to himself.

Limited and fanatical by nature; cramped by long service in a narrow field of labor; feeling voluminously, but thinking neither comprehensively nor rationally; toiling ever in the penumbra, if not the shadow, of superstition; habitually personifying phenomena, and ascribing general conditions to special antecedents as causes; having witnessed with increasing dismay, from year to year—in his professional as well as his civil capacity—the unstayed ravages of this apparently pitiless and unsparing monster—invading every land and every household—insidious

as pestilence; greedy and insatiable; feeding like a fabled dragon, with ever increasing appetite, upon all that is estimable in human nature; imperishable, and many-headed as a hydra; from whose many mouths proceed, incessantly, falsehood, delusion, violence, and crime; each giving instant birth, in turn, to all manner of kindred but ever-varying vices; it is not to be wondered at that he should so believe; nor that, being so filled, he should go his way vituperating alcohol, and all persons not already enlisted in a crusade of extermination against it—however hopeless of success the fanatical adventure. The measure of his understanding is full. It were folly to overflow it.

The next man, closely related to the first by capabilities, education, and experience; differing, temperamentally, only so far as to be able to accept the inevitable with less friction, or emotion, will insist that the insanity of civilization is a result of overwork, and mental strain, and other incidents of modern life, characteristic of a 'fast age and greedy people.'

In addition to an exhaustive arrangement of our most active and enterprising business men, because of their habits, and methods, of accomplishing ends without regard to means, or consequences—straining every fibre of being in pursuit of unworthy objects, success outweighing every other consideration, he may be expected to impeach everything modern without discrimination or reason. Under present circumstances, as the world seems to him to be wagging, women are everywhere disqualifying themselves for healthful maternity (the chief end of female existence) by unreasoning devotion, in their social relations, to absurd fashions; and criminal violation of natural and statutory laws in their relations of wives and mothers. Men are as unmistakably deteriorating, physically and mentally, because of such "maternal delinquencies," and their own acquired habits of life. And children are being dwarfed, or destroyed, by thousands, through the instrumentality of modern schools, and newfangled notions respecting the education of youth—both methodical and institutional.

"Doctor of Medicine" though this man be—and presumably familiar with the fact, if not its significance—that an evolution of science has been taking place within his time, by which old opinions and beliefs have been, and are being, revolutionized; his own profession, even, metamorphosed, dignified, and advanced—he is one of those, nevertheless, who are being carried forward by the stream of human progress somewhat reluctantly; lagging in the rear of the advancing column of humanity—marching like a discontented soldier in retreat, with vizzor reversed, looking ever rearward. Intellectually myopic, he sees neither before nor after, to any considerable distance. He is not without his uses.

The burden of the third man's response will be an ascription of insanity to the general disorder of society incidental to existing forms of government and social customs; it being one of the penalties inflicted by nature upon mankind for violations of natural laws of justice and equality—effected more immediately by the excesses of the stronger, indulged while rapaciously feeding upon and devouring the weaker; and the privations that the weaker (and worthier) are compelled to suffer that the strong may luxuriate. All characteristic, he will say, of civilization.

Intellectually a hybrid—a mixture of philosophy and lunacy—this man sees no prospect—no possibility—of anything but disorder, under existing circumstances—and wonders, only, that more persons do not "go mad." As he sees things now, all governments are despotic, cruel, and unjust; established by usurpations of power, and maintained by violence and fraud.

The corner stone of each is a denial of the natural, inherent "rights of man," individual and social; upon which rests a superstructure of fictitious distinctions, and class privileges, abhorrent to justice, and obnoxious to the welfare of the race. All institutionalized religions as he sees them, are alike dogmatic and intolerant; affecting recognitions of the "fatherhood of God, and the brotherhood of man,"—but practically, historically, denying such recognitions; and representing God as an immensely magnified human despot, and but a few select people as worthy of divine favor. So, too, all social organizations are outgrowths of erroneous ideas respecting the natural equality of human beings, and their rights and duties under all circumstances, in every relation of life.

Our fourth respondent—a modern specialist by chance—may be expected to assert, with characteristic energy, and apparent sincerity, that one half of the insanity to be met with now-a-days, is attributable to untreated surgical diseases of the reproductive organs of women; amenable to treatment, generally overlooked by ordinary practitioners, and wholly neglected by the medical officers of our hospitals and asylums for the insane.

Congratulating this man, and his confrères in opinion, upon so great a medical discovery, including the localization of mental function in the female organism, presuming, analogically considered, that the other half of insanity, not accounted for gynæcologically, is ascribable to diseases of the male organs of reproduction, we may profitably pass to an examination of the next "expert," however superfluous further inquiry may appear to be.

The fifth interlocutor—he may as well appear now—to whom the problem under consideration appears to be exceedingly simple—will maintain, with an air of conscious superiority, the asser-

tion that insanity, in all of its phases, is but an upsetting of feeble-minded persons by trivial circumstances; such as disappointment in love, loss of property, or friends; grief, jealousy, or religious fervor; fear of hell, and the like; because of their ignorance, and lack of common sense. He thinks that people "go crazy" on certain subjects, such as religion, spiritism, christian science, or some other form of fanaticism; leaving out of consideration any possible morbid material element, however important such consideration may be to a scientific solution of the problem.

Superficial, vain, voluble, vulgar, probably profane; it may be anticipated of this man, who has never really thought of insanity as having any definite relation to civilization, that while casting about for material wherewith to amplify his discourse, he will bethink himself of sexual excesses and abuses as causes of insanity, and having struck the dead-level of his intellectual tastes, that he will descant indefinitely upon the familiar topic of sexual appetites and indulgencies; relating many anecdotes, and bringing into bold relief the fact that he looks upon all emotionally pious, as well as hysterical women, as erotic; all spiritualists as "freelovers;" and all ministers of religion as lascivious, if not licentious.

Fortunately, we do not have to listen to all that such men have to say, and may so leave him to indulge his own egotism and vulgarity, while we interrogate a worthier, if not a wiser man.

And here he is—slow and irresolute of speech at first, gaining time, as it were, for reflection, we need not be surprised by a final announcement of the conclusion, that civilization has nothing to do with insanity, generally or specially considered. Nor by the assertion that, according to his personal observation, nearly, if not all insanity, is of syphilitic origin. Candid, conscientious, resisting plausible testimony, fearing to be misled, he will attempt to fortify his position by facts; stating that he now recalls a great number of cases of insanity caused by syphilis—many—several—two or three—one well marked case; that of a man, about 45 years of age, who had, etc., etc. When a worthy brother begins to recite clinical history, from memory, in support of an absurd proposition in medicine, he is liable to become tedious.

Should we meet a seventh witness in this line of investigation, let us hope that he may be a man who has had sufficient mental training to comprehend the full purport of a question when plainly stated; as well as one who has dug through all merely superficial indications of valuable matter, and struck his intellectual pick into a matrix of pure ore. Not that surface indications are of no value. To an experienced miner they may be of great significance. But incompetent observers are liable to overestimate their intrinsic

worth, or to mistake them for wholes of which they are but fragments. The uninstructed, indeed, often deceive themselves by holding fragments of truth in such relation to the eye as to permit them to occupy the entire field of vision. It is thus that the massive sun is sometimes totally eclipsed by the tiny fragment of a world, called the moon.

But what need of further illustration? No well-informed man, capable of weighing testimony, and applying general principles to special subjects, can fail to recognize the lack of breadth and comprehensiveness of commonly entertained views of the subject before us. Nor will it escape his observation that, vary as they may, they are all of the same general type, or purport; each consisting of certain limited speculations respecting the relation of insanity to certain "exciting causes," without an allusion to any inferentially essential precedent, constitutional preparation for the efficient action of such "causes," or the part played by civilization in effecting such conditions. While the fact is, not one alone of all the many exciting causes of insanity—not all of them combined—can produce the phenomena of insanity by their influence upon other than exceptional persons. Nor can all of the facts pertaining to the subject be taken into consideration and harmonized, by such limited speculations, however satisfactory they may be to those who entertain them.

It is a fact, for example, that neither alcohol, nor alcoholic intemperance, is peculiar to civilization. It is a fact, also, that alcoholic intemperance has been steadily decreasing among the more highly civilized peoples, for half a century or more, while insanity has been as steadily increasing.

It is a fact that our hospitals and asylums for the insane are populated, almost exclusively, by very ordinary people; men and women who have never suffered great vicissitudes of any kind, undistinguished persons, who have neither aspired nor endeavored, struggled nor attained, to any considerable extent, in any direction.

It is a fact that while men may, and do sometimes, destroy themselves by overwork and mental strain, in their pursuit of wealth, or fame, or means of personal distinction or enjoyment, not many ambitious, capable, successful men of affairs become insane, however effected, or premature, their dissolution. Rare exceptions to this rule attract attention because of their rarity.

It is a fact that the opulent and luxurious, who have become such by personal enterprise, sagacity and acquisition of means, however destructive of morals, or of health, their habits may become, do not, many of them, become lunatics.

It is a fact that, while pelvic and abdominal diseases of women are more frequently and intelligently recognized by the profession now than

formerly, and, because of modern modes of dressing, and pernicious habits of preventing conception, or arresting gestation, on the part of many women, they may be more numerous and prevalent, it may also be affirmed that more women, ten to one, have been consigned to hospitals for the insane—victims of needless or unskilful surgical operations, performed by ambitious and pretentious gynecologists, than have ever been restored to reason by the most commendable and skilful abdominal surgery.

It is a fact that no people have ever achieved greatness, or accomplished anything worthy of existence as men, without government—the worst being better than none—and it is likewise true that all civilized governments have been growing more and more beneficent, more and more considerate of the welfare of the governed, of all classes, for the past hundred years or more; growing in grace with the evolution of rationalism and morals that has characterized the present century; extending their blessings, more especially, to the weaker and more dependent classes.

It is a fact that “our time” is notable for its freedom from fanaticism, and the grosser features of superstition; there never having been a time before—strange as it may sound to the worshippers of antiquity—when the world was so nearly rational as it is now.

It is a fact that, historically considered and contrasted, this is not a licentious age, nor are we a lascivious people. Nor is syphilitic contamination, thanks to science and a more general diffusion of useful knowledge, nearly as extensive or destructive now, as it was formerly, among civilized peoples.

It is a fact that savage peoples have been, and are now being, decimated, if not annihilated, by the ravages of syphilis—notably the native Hawaiians, and Alaskans—conveyed to them from civilization, without any history of concomitant insanity whatever.

It is a fact that while the longevity of individuals has not increased by, or with, the progress of civilization, the longevity of the race, so far as affected by civilization, has increased, owing to modern triumphs of peace over war, of science over pestilence, of reason over superstition, and a constant increase of food-supplies, and betterment of habiliments, including all manner of habitations, and the consequent survival of large numbers of persons otherwise destined to inevitable extinction.

How, then, does civilization affect the conditions of mankind—what does it do to men, physiologically or historically considered, whereby they are rendered more liable to become insane, than are savages or barbarians?

The answer, so far as present knowledge enables us to answer intelligently, is neither difficult nor complex. It is this:

Civilization, by its extensive and intricate co-operative combinations and activities—its arts, sciences, inventions, ethical perceptions, and consequent benefactions, not only rescues from otherwise inevitable dissolution, but nurtures, matures, and enables them to multiply by reproduction, multitudes of organically defective individuals, of the human species, in whose structure inhere certain potentialities, not common to the race, but essential to the manifestation of the phenomena of insanity, under any given combination of circumstances.

This answer is both explicit and comprehensive, and harmonizes, not only the facts already recited, but all facts pertaining to the subject, among which the following are offered as authenticated and suggestive, viz.:

The fact that all peoples now classified as “civilized,” have become such by transitions from barbaric and primitive conditions; there being no evidence acceptable by science, that any originally civilized people ever existed, or that any people having become civilized spontaneously, ever relapsed to primitive, or intermediate barbaric conditions.

The fact that man, as related to the universe, is not an exceptional being, but subject to the same general conditions and contingencies that determine the becoming, continuance and disappearance, of all other specializations of living matter.

The fact that the same germinal and seminal prodigality that characterizes nature everywhere, forcing into being multitudes of superfluous individuals of varied capabilities, for whose subsequent development adequate provision has nowhere been made, necessitating an inevitable and immediate conflict and “struggle for existence,” in which the weaker, or otherwise defective, must necessarily perish, is characteristic of mankind, as well as of other animals of the same order.

The fact that the first intelligent effort of mankind (called “instinctive” when exhibited by lower animals), to mitigate the severities, and supplement the deficiencies, of nature respecting the welfare of the race, consists of coöperative combinations of individuals for the accomplishment of ends otherwise unattainable; such as the capture and appropriation of food-animals, too strong or ferocious for individual prowess, or defense against enemies of like character seeking to make food of them; combinations by which two or more individuals are enabled to live where but one could have existed under other circumstances—the weaker ever being, if existence is to them a benefaction, the real beneficiaries.

The fact that all subsequent, successive, efforts of mankind, having in view the conservation of individual existence, instigated by organic sentiments, or love of life, of self, of offspring, and finally of the race, resulting in the various phases of civilization, are but extensions of, or evolu-

tions from, primary, simple, coöperative combinations of individuals, whereby the disastrous indifference and negligence of nature have been supplemented, and counteracted, in an ever-increasing ratio.

The fact that in the transitions from primitive conditions to civilized states, common to all civilized peoples, a constitutional diversification of individuals, as in the domestication of lower animals (a similar process), always takes place, corresponding in variations from original types to the degree of cultivation reached at any given time, finally necessitating recognitions of classes, or breeds, consisting of individuals presenting certain peculiarities, sufficiently similar to relate them as a group, while, at the same time, distinguishing them from the common stock. Classes among civilized peoples whose characteristics elevate them above the common level of humanity, and classes correspondingly depressed.

That the insane constitute a "class" of society cannot be rationally denied; inasmuch as the constitutional conditions essential to the manifestation of the phenomena of insanity do not obtain uniformly in the development of mankind—but few only of a given number of persons being capable of manifesting them.

That the insane, as a class, are defective, is also self-evident; defective manifestations of phenomena always implying defect of mechanisms, the activities and conditions of which are thereby reflected, the mechanisms of mind not excepted.

The constitutional peculiarities of the insane are, likewise, correlatable with the peculiarities of other defective classes of society, such as the anatomically asymmetrical, the physiologically unstable, the intellectually incompetent or eccentric, and others whose abnormal conditions find expression, phenomenally, otherwise than by manifestations of mania, melancholia or dementia; responding to excitation, sometimes, by exhibitions of hysteria, epilepsy, neuralgia, or uncontrolled impulses to irrational violence, unresisted propensities toward sensuality or intemperance, and not infrequently, a general perversity of feeling and perception, constituting the diathesis of crime.

The inference is therefore forced upon us, and may not longer be resented, that with every increase of coöperative complexity and activity—embracing larger and ever larger aggregations of individuals, with increasing comprehensiveness of purpose, and efficiency of action—attended by continuous growth of capability and accumulation of knowledge, from which evolutions of humane sentiments and ethical perceptions are inseparable, the number of individuals rescued from premature dissolution will increase, and the lower will be the stratum of "unfitness" from which such rescuing will take place.

What! Insanity, and other blemishes of civilization, attributable to the apparent benefactions, instead of the evident malefactions, of civil life? Impossible! Good and evil are not so closely and inextricably related.

So it may seem to the multitudes whose notions of good and evil are as incoherent as their knowledges of the universe are limited and superficial. But no well-informed, thinking man will shrink from the conclusion. The law of compensation is never suspended. Mankind can afford to accept the facts, or conditions of civilization, even as thus depicted. Reciprocity is the highest practical ethic of which mankind is capable. Public as well as private charity is quite as beneficent in its influence upon the doers, as upon the intended receivers of benefactions. He who neither apprehends the past nor trusts the future, is liable to suffer irrational doubts, and groundless apprehensions.

Civilization as a whole, or general condition of human affairs, is harmonious, however discordant its component features may appear to be when considered separately, or unrelated.

The higher and lower degrees of civilization are as continuous, yet discreet, in their relations, as are the upper and lower surfaces of any object geometrically considered. Whatever is higher, ideally or materially, grows out of, rests upon, and is inseparable from, that which was before, and is lower, or beneath.

He who should anticipate ripened fruit, without the necessary antecedents—blossoms, leaves, twigs, branches, stems and roots of a perfect tree, would be scheming both ignorantly and idly. He schemes as ignorantly and idly who hopes or expects to attain and maintain a high degree of civilization without a long series of antecedent lower degrees, with which the higher must remain forever continuous. Disrupt civilization as it now exists, and separate the highest attainment from its antecedents, as we pluck fruit from trees, and it would as inevitably, if not as speedily, begin to perish. We cannot think of civilization as thus dismembered, if we try, without confusion of thought.

As an illustration of civilization as it now is, take for example any great city of the world. It is a perfect illustration. Barbarism never built a great city. Look at its population! The richest and the poorest, the noblest and the vilest, the strongest and the weakest of mankind are here inextricably, yet discreetly and harmoniously, associated. Look at its streets and buildings! Temples, palaces, and magnificent mansions, with all of their accessories, many and beautiful, are here! But miles on miles of narrow, filthy streets, flanked by common dwellings, cottages and hovels, constitute an inseparable corollary. Imagine now, if possible, a transformation! Wave the magic wand of ideality, and

behold! these buildings all converted into palaces of equal beauty, sumptuousness, and magnificence! And these inhabitants—all transfigured! all strong, noble, intelligent, learned, rich, luxurious, free, and secure in every right or privilege acquirable by man! Alas! such a condition is not maintainable! Humanity may be crushed, but cannot be elevated, to a common level. Crush society to a common level, and the result will be a common condition of barbarism or brutality. Utopian philosophers and pious dreamers, of all ages and nationalities, have imagined and predicted the coming of all manner of impossible conditions of society, equally chimerical, because implying unification of human qualities, capabilities and necessities, and a final solidarity of good, and disappearance of evil. But whether pietistic or political, such prophetic dreams have ever been discredited by disappointment, as they ever will be, so long as the conditions of mankind are determined by growth and environment, and not by miraculous interpositions of hypothetical influences, which cannot be rationally contemplated, because of implied disturbances of the relations of sequences to antecedents, which it is impossible to regard as otherwise than inevitable.

ARE CONSERVATIVE AMPUTATIONS ALWAYS IN THE BEST INTER- ESTS OF THE PATIENT?

*Read before the Mississippi Valley Medical Association, St. Louis,
Mo., October 16, 1891.*

BY CHARLES TRUAX,
OF CHICAGO.

In pre aseptic days, amputations were properly governed by an inflexible rule which taught that the first duty of the surgeon was to save every possible ounce of tissue, because, first, experience had demonstrated that the nearer the point of amputation approached the trunk and the broader the stump, the greater the risk of life; second, it was generally believed that in all cases the usefulness of a stump increased with its length.

These principles, still taught in all of our standard text-books (save one) and having been practiced by every eminent operator from the first records of surgery down to the days of asepsis, are in general use to day—although the conditions forming the basis for their advocacy no longer exist, at least in their former weight and importance.

The first of these principles was formulated at a time when pyæmia, septicæmia, or like complication endangered the life of nearly every patient who submitted to an amputation, so that even if the patient survived both the original condition and the operation, his life was still in danger from some one of these dread maladies.

It was found that this danger increased with the size and extent of the wound, so that surgeons were unconsciously led to vie with each other in their efforts to amputate with the least sacrifice of parts.

When the principles promulgated by the eminent Lister came into general use, they practically sounded the death knell of those forms of disease resulting from external wounds, and rendered obsolete the infallibility of the so called "golden rule" which taught conservatism in amputations under all circumstances, for statistics collected from the records of nearly one thousand surgeons, embracing only such amputations as have been performed since 1885, prove conclusively that there are at least some exceptions to this rule.

Admitting it to have been a fact that, in the earlier history of prosthetical art, the longer the stump remaining after an amputation the greater was its value, it does not follow that it is so today, and I trust to be able to demonstrate that in some classes of cases and with certain limits the value or usefulness of a stump actually decreases with its length.

During the past quarter of a century the development of prosthetical science has advanced with a rapidity unprecedented in the history of the art. The first of the two great causes which stimulated this development may be found in the dreadful carnage and mutilation observed in the late Civil War which left thousands of veterans maimed by the loss of one or more limbs, for whom it was necessary to provide artificial substitutes.

The second, and now the most important factor in producing injuries necessitating amputation, is the great increase in the volume of machinery in use and the velocity with which much of it is operated. These two causes, combined with others of minor importance, have increased the demand for artificial limbs and developed a competition that has called forth the best efforts of our inventors, resulting in improvements so wide and varied in their extent as to place American artificial limbs, in point of efficiency and durability, second to none. To so high a state has the art been advanced that, under favorable conditions, makers of such appliances are enabled to construct artificial legs that permit the wearer to live and move in society without his being known or considered as a cripple.

An examination of a given number of applicants for artificial legs will, I think, demonstrate that only a moderate number are what may be termed favorable cases; *i. e.*, those permitting the use of the most perfect and complete forms of mechanism. Aside from these, a fair number could be selected for which limbs could be constructed that would furnish means for locomotion which, though more or less imperfect, would

be accepted by the patient as the best results that could have been provided, on account of the nature of the disease or injury. The balance of these applicants (and of the three classes they would scarcely represent the minority) can, at best, only secure unsatisfactory or miserable means of support, and for these subjects, unless they be in quite comfortable circumstances, life can only promise to be a burden.

Experience and investigation has convinced me that the percentage of favorable cases can be largely increased provided surgeons will familiarize themselves with the necessary mechanism of ordinary artificial legs and the relations existing between them and the stumps on which they are to be worn, and select their point of amputation accordingly.

If, out of a given number of cases, say only one third of them are at the present time favorable ones, is it not possible to largely increase the number by amputating only at points which will provide stumps that are favorable? And if this be possible, is it not the duty of surgeons to familiarize themselves with these points and the reasons for their selection and, as Stephen Smith has well expressed it, "Have a humane regard for humane surgery?"

Notwithstanding that the old Golden Rule has been firmly impressed upon the minds of graduates and practitioners by the writings and teachings of standard authors from time immemorial, it is still a fact that a fair percentage of the more careful, conscientious and progressive surgeons of the present day have for some time been operating to a greater or lesser extent on an entirely new system—not only a new system but one that is in direct opposition to the ideas and principles that for ages have been accepted without question.

The old system as previously stated, was in all cases to perform an amputation with the least possible sacrifice of parts. The new system does not interfere with this in stumps for prehensile purposes, but in operations in the lower extremities it teaches that amputations should be made at such points as will enable instrument makers to construct the best possible form of artificial substitutes even if in so doing the surgeon removes tissues that, under former methods, would have been permitted to remain. The question of saving an inch or two, or even more, in the length of a stump is of no importance if its removal will secure a stump permitting the application of a more perfect and satisfactory appliance.

The conditions essential to a favorable stump for locomotion are a conical form without sharp corners or protuberances, with cicatrix underneath and preferably at the posterior margin, and length enough to obtain a good bearing in the stump socket. If these requirements are

complied with and the stump possesses the necessary firmness to bear the contact with the socket, the patient, if properly fitted, will be enabled to operate the artificial part of the member in such unison with the natural portion that detection of the former is almost if not quite impossible.

Fig. 1. Showing Section of a Thigh Socket.

The section of a thigh socket here shown will, I think, show why it is necessary that leg stumps should be of a conical form and may, at the same time, demonstrate that our text-books are in error when they teach that stumps should be so formed that they may bear more or less of the weight of the patient on their ends. When a section has been made through a bone, if the cut surface be not covered by an osteoplastic operation, no weight can be borne on the end of the stump. If surgeons will make their amputations at proper points not one ounce of weight need be carried by patients on the ends of their stumps.

It is a fact easily proven that, in most cases where a stump is so formed as to necessitate its bearing a portion of the weight of the patient on its end, it is usually a source of annoyance, because it not only forms an inferior means of support, but as the late Dr. Gross well expressed it, "it is constantly liable from the slightest causes to pain, irritation and ulceration."

As the internal diameter of a well formed socket decreases from above downwards (see illustration) and as its carrying power depends largely on the lateral pressure of the stump against its converging walls, it is evident that if the stump be of a conical form it will distribute the weight or pressure surface over a larger extent of the limb.

These sockets are carved or cut from the inside and so shaped that they fit the exterior of the stump as accurately as a kid glove does the hand, consequently the more circular the stump and the more nearly free it is from all uneven surfaces, the more perfectly it can be adjusted.

The position of the cicatrix must depend largely on the method employed in the operation. In selecting this method the surgeon should, by all means, locate the cicatrix to one side of the end of the bone and posteriorly if possible.

In amputations of the femur the value of the stump to the patient increases with its length until it reaches a point where this length precludes the use of what is known as the long or cylindrical form or joint.

In order, then, to choose the proper point in amputations of the lower third of femur, it is only necessary to learn the amount of space requisite for the working of this joint and where possible if there be no increased risk of life, operate

accordingly. By actual measurement, we find that in an adult this joint can be inserted and successfully used in an artificial limb provided three inches are removed from the lower end of the bone. Here, then, is the point of election and the one that should be adopted if circumstances be favorable.

In amputations of the tibia, the value of the stump also increases with its length, and the same rule should be applied as in the case of the femur, excepting that the point of election should be the juncture of the lower and middle thirds. Here the amount of surface exposed to the lateral pressure of the socket is not of as much importance as in thigh stumps, because the weight of the body is principally carried by the condyles of the head of the tibia. These afford a firm, unyielding surface which, when once well fitted with a socket, will, if necessary, carry the whole weight of the patient. It is, however, preferable to secure the advantages of a natural, conical-shaped stump by amputating below the calf, and thus increasing the bearing surface, and removing a part of the pressure from the head of the bone. Further, the amount of leverage increases with the length of the stump, so that if the operation be performed at the point indicated, the patient will have better control over the artificial limb than if the operation be at a higher point.

This point of election not only gives to the patient every benefit offered by amputations at or near the ankle, but it enables the instrument maker to display his mechanical ability to the greatest possible advantage.

Following injuries involving the middle and upper thirds of the tibia, many works on surgery advocate the leaving of short tibial stumps, that the patient may be provided with what are known as knee-bearing legs, or those in which the weight is taken on the anterior aspect of the flexed limb. It seems almost unnecessary to present arguments to demonstrate that such limbs would be clumsy appliances at best, owing to the imperfect connection between the natural and artificial portions. Short tibial stumps usually contract to a greater or lesser extent, and for this reason should be avoided. I would say that an amputation should not be performed within 3 inches of the joint. In cases where only from 3 to 4 inches of the tibia can be preserved, and there be no danger from inflammation in the joint, it would seem better, from my standpoint, to excise the remaining portion of the fibula. Its presence is of no benefit to the patient, while its removal facilitates the forming of a more conical stump, and insures a greater degree of firmness therein. Several cases have come to my knowledge, where the pressure of an artificial limb socket on the remaining fragment of fibula has proven a constant source of pain and discomfort, and one or two cases of ulceration I believe were due to this cause.

The fundamental principle that forms the basis for the new theory is the fact that the successful operation of a limb, whether natural or artificial, depends largely on the action of its joints. Therefore, unless the surgeon amputates at points that not only leave the natural joint intact, but provide below it sufficient leverage to swing the substituted portion, he will interpose obstacles in the way of the instrument maker that will prevent the construction of the best form of appliance.

To amputate through the knee or ankle-joint is to assume the position of the dog in the manger, for the remaining structures occupying the half of the space of the joint are of no use to either the surgeon or patient, but take up room that should be used for joint mechanism. The natural half of a joint remaining after a knee or ankle disarticulation is of no more use to the patient than the odd half of a pair of shears, for only in a limited number of cases can much, if any, weight be borne by the ends of the bones.

It is true that external knee-joints of the carpenter's rule pattern, such as are used in deformity braces and a sample of which is here shown (Fig. 2), can be employed after amputations either through or close to the articulation. Experience, however, has demonstrated that this joint is not a suitable one for long continued service if compelled to carry a weight.

The bearing surface of the cylindrical joint is at least twenty times greater than the rule joint, and from its construction it is so much stronger that it seldom gets out of order.

It required only a brief experience in the construction of artificial limbs to satisfactorily demonstrate to my mind that patients in large numbers are being crippled annually by tarsal and tibio-tarsal amputations, but it was with considerable hesitancy, even after an extensive investigation, that I first dared to advise the entire abandonment of all operations of this class.

My researches extended through the range of mechanics, I examined the laws governing the physiology of locomotion, inspected patients and their appliances from an esthetical standpoint, investigated the relative first cost of the various forms of compensative apparatus, and the approximate yearly expense necessary to keep them in order, collected statistics showing comparative results following tibial on the one hand, and tibio-tarsal, tarsal and tarso-metatarsal amputations on the other, ascertained the risk of life in these two classes of operations, and liability to re-amputation, and placed on record, for the first time, statistics showing the practical value to the

Fig. 2. Showing Rule Bearing Joint.

patient of these two classes of stumps, and in each instance arrived at the same result (*North American Practitioner*, July, 1891); and I stand here to-day in defense of this position, knowing that, so far as I have any knowledge, I am opposing the teachings of every standard work on surgery except the writings of Stephen Smith.

From a mechanical standpoint, we find the same principles operating in the case of the ankle as in the knee-joint, and unless the stump be short enough for the insertion of some form of a cylindrical joint like the one here shown

Fig. 3. Showing Cylindrical Joint.

(Fig. 3), or its equivalent, the manufacturer is compelled to resort to the rule pattern previously referred to. The latter, besides wearing away quickly, will not withstand heavy lateral strains. The operation and use of these rule joints is very unsatisfactory to the patient, and the necessity for their use should be avoided.

The laws of the physiology of locomotion show conclusively that the foot, or a portion of it, cannot be adequately substituted. It is true that Syme's operation will admit of the use of a whole artificial foot, but as its successful operation must depend on certain forms of construction and methods of attachment, unless there be space for the insertion of such mechanism, the foot will be more or less helpless and the patient crippled. Ease and grace in walking are not attainable unless the lower limbs are provided with levers or propellers by which the body is moved forward. Remove these levers at or below the ankle, and the patient is compelled to assume an awkward, limping gait, even if assisted by the best artificial substitutes made.

The principle of the lever is well exhibited in the flexion and extension of the foot while walking, the foot itself being the lever, the Tendo-Achilles furnishing the power, the ground the fulcrum, and the body the weight to be moved. To take a complete step forward necessitates the raising of this weight, because the trunk, at the time when the forward foot is planted on the ground (being then midway between its two

oblique supports), has dropped until the pelvis is on a lower plane than before the step was commenced. The completion of the step requires the raising of the trunk to its original level. This elevation of the body is accomplished by the exercise of the lever power, because the extension of the foot then in the rear forces the body forward until the trunk is in a position perpendicularly over its advanced limb, and the step completed.

In walking, the heel and ankle rise on the ball of the foot, and by the lengthening of the limb caused by the extension of the foot, the body is forced forward, and is raised by the changing of its supporting limb from an inclined to an upright position. This falling and raising of the trunk produces the undulating motion so noticeable in walking.

If one or both of these levers are amputated at points where they cannot be artificially replaced, an awkward, limping gait will result. If one lever be removed, it becomes necessary for the patient to take a shorter step with the sound limb, otherwise he would be unable, for want of the extension previously referred to, to complete the movement—at least, without undue exertion. It is evident that the longer the stride, the lower the level reached by the pelvis, just as increasing the length of the base of a right angled triangle decreases the height of the perpendicular, provided the hypotenuse remains the same. The taking of a short step with the sound limb, however, does not entirely compensate for the loss of a foot, but usually compels the patient to adopt a lurching movement of the body. This lurching, due to rotation of the pelvis upon the hip of the sound limb, is frequently assisted by a greater flexion and extension of both knees. These movements, whether made use of singly or conjointly, are directed toward the accomplishment of the same result, viz., the forward propulsion of the body, and the consequent elevation of the trunk until it has reached the level occupied by it before the step is commenced. Patients who have suffered amputations of this class, after being provided with artificial substitutes, rarely walk as well (and to walk at all requires the outlay of more labor) as where the amputation has been performed through the tibia. I have examined several patients with double tarsal amputations, and in each instance found them taking short, mincing steps, while those with double amputations of the tibia usually take full-length steps.

From a financial point of view, artificial limbs for Symes operations usually cost as much as if made for amputations at a higher point, but stumps resulting from osteoplastic, sub-astragoid, medio-tarsal and tarso-metatarsal operations can be furnished with appliances at about two-thirds their cost. A full-length artificial limb,

however, *i. e.*, for amputation above the ankle, can be purchased from most manufacturers with a five years' guarantee as to durability, during which time it will cost practically nothing to keep it in order. Such a limb will wear from five to twelve years, while those for stumps ending at or below the ankle will usually last only from two to four years, and be out of order a good part of the time at that.

More important than, or rather the cause of the loss of the lever principle following tarsal amputations, is the breaking down or total removal of the arch of the foot, and it matters not which one of the specific operations of this class is employed, nothing is left of the arch that affords even a slight degree of elasticity; in short, the string of the bow is gone and the bow itself broken.

From a statistical point of view, I find that out of 2,135 tibial amputations reported to me as being performed between the years 1885 and 1891, 90.7 per cent. resulted in healthy stumps; 3.1 per cent. suffered re-amputation, while 5 per cent. died, leaving only 4.3 per cent. of stumps (including the re-amputations) upon which compensative appliances could not be worn. Of these tibial cases, 962 were seen by the surgeons after they were wearing, or had attempted to wear, an artificial limb, 86.9 per cent. of which walked with an easy movement and a comparatively graceful step.

Of 658 tarsal and tibio-tarsal amputations reported at the same time, 82.7 per cent. resulted in sound, healthy stumps; 8.3 per cent. underwent re-amputation, while 3.2 per cent. died, leaving 14 per cent. (including re-amputations) upon which prosthetical apparatus could not be worn. In this class of cases, 169 were seen after attempting the use of compensative appliances, 54.4 per cent. of which could walk well.

If we can judge correctly from the foregoing statistics, in every 100 cases of each of these classes of operations, we may reasonably expect the death loss to be in favor of tarsal operations as 5 per cent. is to 3.2 (but it must be borne in mind that in the majority of these cases reported the tibial operations were performed in preference to the tarsal, because of the greater extent of the injury, and the difference in mortality may safely be attributed to shock or complicating injury, and not to the fact that the operations were made nearer the trunk), while the ratio of re-amputations necessary will be in favor of tibial amputations as 8.3 is to 3.1. The number of healthy stumps resulting from these operations would be in favor of tibial operations as 90.7 is to 82.7, while the number of unhealthy stumps would also be in our favor, as 4.3 is to 1.4. Of those who attempt to wear artificial substitutes, we may expect to get favorable results in 82.9 in tibial and 54.4 following tarsal operations.

Owing to the unsatisfactory service resulting from the use of artificial arms and hands, the surgeon is not warranted in adopting radical methods in treating injuries or disease in the upper extremities. On the contrary, he should exhaust the last resources of conservative surgery and save all of the parts possible.

Instead of the old conservative so called Golden Rule which has formed the basis for amputations for ages, I would recommend, from my experience as a manufacturer and from the foregoing review of the question, the following: Avoid amputating within three inches of the knee joint; do not amputate between the metatarsal bones and the junction of the lower and middle thirds of the tibia; at all other points save all you can, and you will, in every case, have done the best for your patients.

In conclusion, I will state that from the evidence at my command, I believe that I am justified in stating that the so called conservative amputations of the lower extremity are not always in the best interest of the patient.

SOCIETY PROCEEDINGS.

American Public Health Association.

Nineteenth Annual Meeting, held in Kansas City, Missouri, October 20, 21, 22 and 23, 1891.

FIRST DAY—MORNING SESSION.

The Association convened in the auditorium of the Warder Grand Opera House, and was called to order at 10 A.M. by the President, Frederick Montizambert, M.D., F.R.C.S., D.C.L., of Quebec.

Prayer was offered by the Rev. Samuel N. Neel.

After considerable preliminary work, the reading of papers was proceeded with.

Dr. C. D. McDonald, of Kansas City, read a paper on

THE CAUSE AND PREVENTION OF INFANT MORTALITY.

He gave statistics showing that infant mortality soon after birth was 20 per cent. One of the principal causes was the exposure to a low temperature—a chilly room—soon after birth. He had been present when it had been necessary to wear an overcoat in a room where a newly-born child was exposed to bathing. Forcing sleep by soothing syrups to overcome the effects of this exposure was another evil. Another trouble was the forcing of food, such as crackers, and water and whisky into the young, inert stomach of the newly born. The mother who

refused to nurse her child from selfish reasons deserved the censure of the community. Statistics show that in the first year the infant mortality when the child is fed by artificial food is 50 per cent. With natural food the mortality was but 10 per cent. The best artificial food was pure cow's milk. Sterilization by chemical process was not thoroughly a success because vital principles cannot be supplied by chemical process, but sterilization was preferable to impure milk.

No starchy substance could be digested in the infant stomach. Starchy infant food is converted by the chemical processes of the stomach first into sugar, then alcohol, and then acetic acid. No sensible farmer would attempt to feed a calf hay. Hay is the natural food for a cow as much as solid food is for a man. Improper dressing—thin clothes—was also a prolific source of infant disease.

Prof. W. W. Daniells, of Madison, Wisconsin, thought that no one should be allowed to sell milk in cities unless he put his dairy establishment under the control of the sanitary authorities.

GLANDERS IN MAN,

was the subject of a paper by Dr. Joseph Sharp, of Kansas City, Missouri.

The doctor classed glanders with acute infectious diseases, such as tuberculosis. The especial feature of the paper was a report of a case which occurred in his practice, and in which he pointed out the difficulty of diagnosis in this obscure disease and gave an outline of the methods for microscopic examination, together with the best methods of cultivating the bacillus of glanders. The paper recommended that for preventing glanders persons who came in contact with horses having open sores or discharges from the nose should disinfect the hand with a solution containing a tablespoonful of equal parts of glycerine and carbolic acid in a quart of hot water, or ten grains of corrosive sublimate in a quart of water. In his report of the fatal case he had treated, that of a painter who became inoculated through a sore on the hand while handling an afflicted horse, the speaker aroused much interest.

Dr. Paul Paquin, of Battle Creek, Mich., in the discussion, reported a collection of seventeen cases of glanders in man which he had collected in the State of Missouri while living there. As an instance of the virulence of the poison, Dr. Paquin told of one man who, driving behind an affected horse, was struck in the eye by a spray from the beast's nostrils, a case of glanders developing rapidly and terminating in the man's death.

Probably the most interesting paper of the morning was that of Chief Justice Horton, of Kansas, on

THE NECESSITY FOR MORE STRINGENT LEGISLATION TO REPRESS EMPIRICISM.

He said that the mountebank of the nineteenth century, with brazen face and clarion voice, travels the length and breadth of the land proclaiming himself as "Diamond Dick," "Indian Bill," "Big Chief," or by some other equally euphonious and ambiguous title as he asserts his skill and disposes of his wares. It might not be justifiable homicide to compel him to swallow his own darksome nostrums, but the present laws are insufficient for his repression and, however beside himself he may become, we can hardly hope that he will so far forget his villainy as to administer unto himself that which he so recklessly deals out to others.

To protect the public, the American Public Health Association should recommend the enactment of statutes excluding from the medical profession those who are not competent by learning, skill and experience to practice, and punishing by imprisonment any who violate the provisions. No one should be permitted to practice medicine or engage in surgery unless authorized to do so by a competent board of government or State examiners.

Dr. R. Harvey Reed, of Mansfield, Ohio, said it was no easy matter for the medical profession to eradicate quacks or *pretended* medical men. Whenever a question of this kind was brought before the legislature the profession had to contend with two prominent factors, viz., the quacks themselves, who furnished large quantities of money, and second, the general press of the country. Why the press? Because the quacks paid the newspapers more money for advertising than the regular medical profession, consequently the press aided the quacks in trying to down the law.

The next paper read was on

WATER SUPPLY AND PUBLIC HEALTH,

by Mr. Allen Hazen, of Lawrence, Mass.; in which the author dwelt principally upon the typhoid fever and cholera germs which infect impure water. Typhoid fever and cholera bacteria are taken into the system through food and drink. Pure water is therefore a necessity. If water is absolutely free from sewage it can be depended upon as being comparatively pure, although many waters not polluted by sewage have been known to breed disease. Flowing streams will partially purify themselves. Reservoirs and long channels where water flows and becomes aerated will not always purify it. Some system of filtration is therefore imperative, and the question to be decided is the best means of filtration. Several systems were described but all were said to be more or less defective.

At the close of this paper, Dr. Henry B. Horlbeck, of Charleston, S. C., presented some vital

statistics from the Southern States, showing the death rate among the colored population to be much greater than that of the whites, and offered a resolution asking the governmental statisticians in preparing their reports, to arrange them so that this fact may be shown. No action was taken on the resolution.

EVENING SESSION.

At this session appropriate addresses were delivered by Gov. David R. Francis, of Missouri; Gov. L. U. Humphrey, of Kansas, and the Hon. John T. Peak, of Kansas City, Mo. Following these came the President's Address, by Dr. Frederick Montizambert, of Quebec.

He said to the medical men of Kansas City and its vicinity the meeting was meant in part as an appeal to quicken interest in the more purely preventive work of the profession, to increase interest in the organization and working of the coast quarantines and health boards by which people are affected; the sewerage of cities; the disposal of garbage and refuse; the purity of water supply; the infectious diseases of animals now known to be closely related to those of man, as well as other much broader questions of modern sanitation.

To the non medical of all ages, sexes and conditions it is an appeal to take a lively and an active part in the great crusade against dirt and disease. In the words of Sir Spencer Wells, "Instruct your mayor and corporation, your clergy, and your own household, that every case of typhoid fever, or scarlatina, of diphtheria or small-pox, of measles or whooping cough, can no longer be looked upon as natural and providential; but that the existence of such preventable diseases is a proof of ignorance and negligence and a disgrace to the country, to the town and the family."

Every one can do a little if only to make one home or one room bright, more cleanly and more wholesome. Sunlight, pure air, and thorough cleanliness are natural enemies to disease germs. These cannot live where they have not their proper food, which is found in dampness, darkness, mould and dirt. The experiments of Koch, Ransome and others prove that the living germs of consumption, when exposed to the sunlight, lose their vitality in a few hours, or even in a few minutes, if the layer in which they are exposed be thin enough, and that even ordinary daylight, if it last long enough, will have a similar effect. There is no sounder philosophy than the old saying that, "There is more health in a sunbeam than in drugs, more life in pure air than in a physician's skill, and that sunlight may fade your carpets, but better that than have its absence fade your cheeks."

The President then paid a tribute to the memory of such members of the Association as had

died since the last annual meeting. He then passed on and briefly reviewed the various contagious diseases as battled with by the health authorities of the country, together with the experiments entered into to overcome them. Asiatic cholera, la grippe, cancer and diphtheria were all touched upon, as well as disinfection and immunity.

SECOND DAY—MORNING SESSION.

Dr. Paul Paquin, of Battle Creek, Mich., read a paper on

VACCINE AND VACCINATION.

Dr. Paquin touched first upon the necessity for absolutely pure vaccine and told of some of the diseases that accrue from impure vaccine. The doctor had tested on rabbits, guinea pigs and fowls over 100 vaccine specimens. In these tests he said he had found such cheerful forms of bacteria as the bacillus pyogenes fetidus, the staphylococcus pyogenes aureus, the bacillus septicus, and gangrene micrococci. These he said produced abscesses, gangrenous lesions, septicaemia and pyaemia.

Dr. Charles N. Hewitt, of Red Wing, Minnesota, spoke of unfavorable results from using bad vaccine in his State and of the difficulty in obtaining good vaccine, and gave his personal experience. Small pox, he said, is the same as it always was. An epidemic might sweep the country now as the country was practically unprotected.

Dr. Yesi, of Mexico, spoke of the compulsory vaccination of Mexico. Human vaccine alone was used. Lower animal vaccine is not cultivated. Better results from human than animal vaccine are obtained. A serious small-pox epidemic has not visited that country in about twenty-five years.

Dr. L. F. Solomon, of New Orleans, La., replied that in Louisiana each child must show a vaccination certificate before being allowed to attend school. About 90 per cent. of the primary vaccinations were successful. He favored the use of bovine virus.

Dr. Delos Fall, of Albion, Mich., read a paper on

THE DISPOSAL OF GARBAGE AND REFUSE.

He spoke of the intimate relation between typhoid fever and the accumulation of waste organic matter. The method used in New York is taking the waste out to sea and dumping it. Philadelphia recommended cremation. Chicago objected to the use of waste in filling holes and vacant lots and then building houses on them. San Francisco recommends cremation. Baltimore has dumps which are objectionable, and which will be removed as soon as a better method can be found. Cincinnati gives its waste to a desiccating company, which is under contract to

remove the same. In Charleston the city removes its own garbage; carts it out in the morning and generally gets through about noon. This waste is dumped into a salt water marsh. The cost is about \$19,000 a year. Milwaukee pays \$23,316 a year for collecting garbage by hand and \$15,000 a year for disposing of the same. The Merz system of disposal of the garbage is used. Garbage is at present disposed of by dumping it into Lake Michigan, much to the disgust of the citizens, because the Merz system contract has expired. In Washington the removal is carried on by the contract system.

Dr. Edward Clark, of Buffalo, New York, made a report on the collection and transportation of garbage and refuse in cities. He advised full police power for the sanitary service of large cities. A galvanized iron tank holding about two or three bushels is the best receptacle for holding household garbage. The refuse tank must not be placed on the street or sidewalk, but the collector should be compelled to go in and get it, remove the contents, and replace the cover.

For transporting, garbage carts are preferable for short, and wagons for long hauls. The beds should be made water-tight, and should be flushed after each dumping. Any driver who failed should be instantly discharged. The bed should be covered with iron.

EVENING SESSION.

The first paper was upon

RABIES,

by Dr. J. J. Kinyoun, of the U. S. Marine Hospital Corps. He said the disease was transmitted almost wholly by the canine and feline species. The disease prevails all over the world, except in Australia, where it is not known. He regretted that so little is known of its prevalence. He opposed the idea that the disease is confined to warm weather, the statistics showing that the greater number of cases occur in December and May. He discussed Pasteur's system and its success. Recognition of the disease is not easy in any animal in the early stages. He advocated the establishment and enforcement of strict quarantine regulations in order to eradicate the disease.

Dr. P. C. Remondino, of San Diego, Cal., read a paper on

AMERICAN CLIMATES AND THEIR PHYSICAL EFFECTS.

He said that it is well known that European immigrants soon lose their ruddy cheeks and bright eyes, with a certain loss of spirit, when they come to this country. They lived in happy disregard of all hygiene or science. In changing climate they followed no national rule whatever for the really necessary change of diet. He then ex-

tolled southern California, and compared it to the Garden of Eden.

A paper on the subject of

ANIMAL DISEASES

was read by Mr. Ernest L. Dundas, U. S. veterinary inspector at the Kansas City packing houses. He spoke strongly against the evil of diseased cattle being shipped to market. As soon as a farmer discovers that tuberculosis is about to ravage his cows, he immediately ships them off to market to get rid of them before they die on his hands. He recommended the police supervision of all milk dairies. He laid to the Jersey cow the blame of being most generally afflicted with tuberculosis.

Dr. Walter D. Green, of Buffalo, said that, while it might not be incorrect that the disease was quite common, and deserved close watching, still, the fact should only urge the physician to more earnestly fight against the spread of disease among his patients.

Dr. Peter Bryce, of Toronto, limited his remarks to tuberculosis in milk, and the manner in which the disease is most commonly transmitted to consumers. In Canada, he said, they never bred their milch cows, and in one city they never use a milch cow after she once goes dry; she is immediately sent to the butcher. The great question is how to tell a cow when she is so afflicted. It seemed to him that in view of the startling figures that there are 15,000,000 cows daily supplying the country with milk, and the fact that in certain abattoirs it has been shown that 5 to 10 per cent. of the cattle killed are tuberculous, there should be a most rigid and regular inspection of all milch cows, as is due the public.

NEW ORGANIZATION OF THE SUPREME BOARD OF HEALTH OF MEXICO

formed the theme of a paper submitted by Dr. Domingo Orvananos, of the City of Mexico. In this paper the outline of work covered by the Mexican Supreme Board of Health was given, showing a most complete system of supervision, a system which, on its face, would tend to make it one of the most thorough in operation in any country. One exceedingly good feature is the sending of a surgeon-physician with every ship leaving Mexican ports, who shall be held responsible for the sanitary condition of the vessel, and who shall be obliged to report to the Mexican consul at every port where the vessel may touch, and obtain from him a clean bill of health. This move was done in view of the fact that Mexico is preparing to meet the reciprocal treaties of all countries, thus calling for the service of an extensive maritime navy.

The session was brought to a close by a paper entitled

LAND HABITATION AS A PUBLIC HEALTH MEASURE,

read by Dr. George Homan, of St. Louis, Mo. The paper showed the benefits which would arise by the individual ownership of homes, as that would render less likely any communicable disease as well as render easier the fight against disease by admitting of isolation, a most desirable feature in combating disease.

THIRD DAY—MORNING SESSION.

Dr. Peter H. Bryce, of Toronto, read a paper entitled

THE PRESENT POSITION OF THE MILK SUPPLY PROBLEM FROM THE PUBLIC HEALTH STAND-POINT, AND SOME PRACTICAL METHODS FOR SECURING SAFE PUBLIC SUPPLIES.

Briefly, Dr. Bryce's summing up of the precautions necessary to healthy milk was thus:

1. It is especially desirable that a system of periodic veterinary inspection be exercised in addition to the dairyman's inspection.
2. Strong views should be held and exercised regarding the nature and quality of food for cows. All decomposed foods, as those which are liable to undergo fermentation, should be wholly avoided. The best foods are well ripened grains and grasses.
3. The stables of the cows are a point of great importance. Too often dark, damp, ill-ventilated and crowded pens have been the home of this chief of our food supplies. It is quite possible to keep even on a large scale a dairy stable free from the ordinary disagreeable stable odors. The water supply to the cows is of equal importance.
4. The care of the milk at the time of taking and subsequently is of all points at once the most difficult and the most necessary to supplying a wholesome milk. De Claux has said: "*Cleanliness is everywhere the *sine qua non*."*
 This means almost a revolution amongst farmers and dairymen. The sterilizing of all cans and bottles by steam or dry heat and the boiling of all strainers will be necessary.
5. The delivery of milk is of prime importance.
6. When milk has reached the consumer it must be placed in a refrigerator or promptly consumed.

FOURTH DAY—MORNING SESSION.

Dr. J. Ramon Ycaza, of the City of Mexico, read a paper entitled "A Few Considerations upon the Progress of Public Hygiene."

Dr. Nezario Lomas, of Moreles, Mexico, followed with a paper entitled

NOTES ON THE HYGIENE OF RICE CULTURE.

Moreles is the great rice-producing State of Mexico, and the paper touched upon the sanitary effects of this culture. The vast rice swamps

were declared by the author to be most unsalubrious.

The report of the Committee on

CAR SANITATION

was read by Prof. W. W. Daniells, Chairman, Madison, Wis. He said the great difficulty in the heating arrangement of cars was that all systems thus devised are for heating alone, and that ventilation is not particularly sought.

Dr. R. Harvey Reed, of Mansfield, Ohio, said that if the public asked for these things, as it demanded fast trains and elegant car upholstery, it would get them.

Professor Daniells thought that cars should be made differently. Instead of covering Pullman cars with expensive tapestry they should be furnished with rattan or leather, as the cars on some of the suburban trains.

Dr. Joseph Sharp recommended comfortable air cushions that could be taken out and cleaned.

Dr. Charles N. Hewitt, of Minnesota, read a paper entitled "The existing methods of dealing with emigrants as respects infectious diseases in England and on English Ships, and the notification of infectious diseases among immigrants to the United States, the duty of the National Sanitary Authorities to the Sanitary Service of the States: an example of such an arrangement between the United States authorities and the State Board of Health of Minnesota."

Dr. A. N. Bell, of Brooklyn, followed with a paper on

"THE BATH AND ITS ADOPTION."

The Executive Committee reported to the Association two important resolutions. One was by Dr. Homan, of St. Louis, declaring it the sense of the Association that State and provincial inspection of the production of vaccine virus be established. The other resolution asks the establishment of a federal department of health, to have at its head a Secretary of Public Health—a Cabinet officer at Washington. Both resolutions passed.

Dr. Henry B. Baker, of Lansing, Mich., introduced a resolution to the effect that the Association hold its meeting in Chicago, in 1893, and that, so far as possible, the occasion be made an international congress of hygiene and public health, which was adopted.

The officers elected for 1892, are as follows:

President, Dr. Felix Formento, New Orleans, La.

Vice-Presidents, Drs. Walter Wyman, Washington, D. C., and Domingo Orvananos, of Mexico.

Secretary, Dr. Irving A. Watson, Concord, N. H.

Place of meeting, City of Mexico, date to be fixed by the officers of the Association.

Southern Surgical and Gynecological Association.

Fourth Annual Meeting, held in Richmond, Va., November 10, 11 and 12, 1891.

FIRST DAY—MORNING SESSION.

The Association convened in the hall of the Y. M. C. A., and was called to order by the President, Dr. L. S. McMurtry, of Louisville, Ky., at 10 A.M.

Prayer was offered by the Rev. D. M. Hoge.

The first paper read was by Dr. J. W. Long, of Randleman, N. C., entitled

ALBUMINURIA ; ITS RELATION TO SURGICAL OPERATIONS.

He drew the following conclusions :

1. That neither ether nor chloroform rarely ever injures healthy kidneys.
2. That when renal disturbances from the use of an anæsthetic, the kidneys being healthy, do occur, they are due rather to prolonged narcosis, exposure of the patient, or perhaps to the combined influences of the operation and the anæsthetic.
3. That a mild degree of albuminuria or nephritis, especially if recent, is not a contraindication to the use of chloroform or ether.
4. That even in the presence of advanced or extensive renal changes, an anæsthetic may be employed, provided the patient or family are advised of the additional risk.
5. That of the two anæsthetics usually employed, it is yet a mooted question as to which is the safer so far as the kidneys are concerned, unless it be in obstetrical operations.
6. That, while it is by no means the rule, profound functional disturbance, and even organic lesions, may be induced by an operation, apart from the influence of the anæsthetic.
7. That such renal changes are due to reflex sympathetic action or sepsis, or both.
8. That operations in certain regions, notably the abdominal, genito-urinary, about the mouth and rectum, are specially liable to produce renal complications.
9. That a healthy condition of the kidneys minimizes, but does not obviate, the dangers referred to.
10. That albuminuria is always indicative of renal lesions, and should be regarded with distrust, but is not a positive contraindication to an operation.
11. That when albuminuria is associated with other evidences of advanced renal changes, no operation should be undertaken without first candidly stating to the patient, or friends, the dangers incident to the condition of the kidneys.
12. That, paradoxical as it may seem, an operation will sometimes relieve an albuminuria due to acute affections.

13. That no surgeon is justified in undertaking an operation without first knowing the state of his patient's kidneys.

SYSTEMIC INFECTION FROM GONORRHOEA.

Dr. Bedford Brown, of Alexandria, Va., read a paper on this subject. He cited five interesting cases of systemic infection from gonorrhœa. He believes that there are two channels for the absorption and transmission of the gonorrhœal microbe into the general system. One is by continuity of surface over the mucous membrane of the genito urinary tract from the urethra to the kidneys. The other channel is through the medium of the great lymphatic system, from the lymphatics of the urethra to the inguinal glands, thence through the lymphatics of the system into the general circulation. He believes also that this microbe, so transmitted, is lodged at different points in the organism. The gonorrhœal microbe transmitted by continuity of surface over the genito-urinary tract, invariably induces specific suppurative inflammation. On the contrary, when transmitted through the lymphatics, the inflammation is not of a suppurative character, but assumes peculiar types; then the contact of the infectious microbe with the mucous surfaces produces suppurative prostatitis, cystitis, ureteritis, pyelitis, and then pyonephrosis. The absorption of the same through the lymphatic channels first sets up lymphangitis of the lymphatics of the urethra, then lymphadenitis of Cowper's glands, then of the inguinal glands, and inflammation of the connecting lymphatics. By further absorption it may induce septic phlebitis of the thigh, and finally synovitis, endocarditis, and internal destructive ophthalmitis. He also believes that, in certain cases, genuine septicæmia may be developed in the course of these complications. He thinks there is marked relative difference in the susceptibility of different constitutions to the systemic poisoning of gonorrhœal infection, as in other diseases. That the absorption and infection of the system from this cause is only in exceptional cases. The writer lays stress on gonorrhœal ureteritis following cystitis, as a part of the action of the gonorrhœal infection in its travels over the mucous surface of the genito-urinary organs towards its final destination in this direction, the kidneys. This complication is accompanied with pain, at times sharp and paroxysmal, usually dull and aching in character. These sharp paroxysms of pain extend upward to the kidney, and not downward toward the bladder, as in nephritic colic. Then again, there is soreness in the entire line of the ureter, increased on pressure, so that the course of the canal may be marked out clearly. Ureteritis is always established before nephritis begins in gonorrhœal infection.

The cases cited by Dr. Brown indicate that a

state of pyæmia or septicæmia may be developed by systemic infection from gonorrhœa in certain cases.

Dr. J. Edwin Michael, of Baltimore, Md., read a paper entitled

A REPORT OF SOME ADDITIONAL CASES OF EXTERNAL PERINEAL URETHROTOMY WITHOUT A GUIDE,

in which he said that the operation is one of great value both in gonorrhœal and traumatic cases, and he thinks one is justified in bringing forward any experience in it which may be of use to the profession. His results were very satisfactory, a fact which he attributed rather to the fortunate circumstance that his patients were largely free from grave constitutional disease, than to any method or application which he had to suggest. He had simply followed what he considered the precepts of good surgery as applied to this region of the body, viz.: free incision, free drainage, and as much of antiseptic surgery as the circumstances would allow.

The report of these eight cases brings up the number of patients on whom he made the operation of external perineal urethrotomy to seventeen, and the conditions which made the operation necessary include nearly all those which ordinarily indicate it. None of the patients have died at a period nearer than six months to the time of operation, and the deaths which have occurred were due to other causes. In the spring of 1887, he reported nine cases of perineal section without a guide, and he had only to add to the remarks made at that time, that increasing experience leads him to have more and more confidence in the good results of opening the perineum, and less fear of danger.

It is true that he had had unusual good fortune in operating on cases which, as a rule, presented no grave kidney lesion, but, while it must be admitted that such complication adds to the risk of the operation as much, if not more, than it does to others of equal gravity, he is firmly convinced that opening the perineum, in old stricture cases with bad kidneys, is much freer from danger than internal urethrotomy, or even dilatation. A case in point. About ten years ago he did an internal urethrotomy on a patient with an old, tough stricture. In forty-eight hours he had a temperature of 107°, and was very ill. The same patient returned to him a short time since. He could pass a No. 10 English sound with difficulty. The stricture was resilient, and closed after the sound to such an extent that urination was difficult and unsatisfactory. The patient had been having chills, and was somewhat nauseated and weak. His urine, although ammoniacal and ropy, contained no evidence of grave kidney trouble. He proposed a combined internal and external urethrotomy, and refused

to do either operation without the other. The patient consented. He opened the perineum freely, and cut the urethra with the Otis instrument to 40 F. The temperature did not rise above 100°; the patient did well in every particular, and in three weeks he sent him home, passing a No. 36 F. instrument on himself.

FIRST DAY—AFTERNOON SESSION.

Dr. W. F. Westmoreland, of Atlanta, Ga., read a paper entitled

REDUCTION OF DISLOCATIONS BY MANIPULATION.

Dr. Joseph Price, of Philadelphia, Pa., followed with a paper on

COMPLICATIONS IN PELVIC SURGERY, AND HOW TO DEAL WITH THEM.

The author's reasons for choosing this subject were that the importance of recognizing the part that complications play in the work of the surgeon are not appreciated by the generality of medical men, by general surgeons, and, least of all, by the tyro in surgery, and by those who are anxious to begin their surgical investigations and trial trips by an entrance into the domain of abdominal or pelvic surgery. The complications in this special branch of surgery are primarily those of surgery in general, with many things superadded to render them formidable. It may be the intention of the surgeon to remove the appendages for a bleeding fibroid. In ordinary operations the removal of the uterine appendages is to the skilled abdominal or pelvic surgeon one of the simplest of undertakings. If, however, he attempts to accomplish their removal without holding in mind the complications that as a rule exist, or if he is a neophyte or an experimental dabbler, he will find too late, in many cases, that he has attempted an operation that he cannot finish, or if he does complete it, he has also sacrificed his patient, or rendered her worse off than before. In other words, to accomplish a cure, must abandon removal of the appendages, and perform hysterectomy, which has but little in common with the operation originally proposed. If this idea is still further carried out, we shall find that complications do not confine themselves to one system of organs, but extend to all surrounding structures, by reason of inflammatory adhesions. This is true of the bladder, ureters, intestines, omentum, stomach, and liver. Adhesions are the bane of abdominal and pelvic surgery, and hence we see that the greatest mistakes and failures are made by those who, from a knowledge of abdominal surgery simply have attempted to deal with pelvic inflammations. The abdominal surgeons who can be counted as really successful pelvic surgeons are, therefore, few. This is said with no intention of detracting from the importance of abdominal surgery. The

strictly abdominal organs must always enter largely into the domain of surgery.

With regard to irrigation, we must get out of our heads the idea that it is dangerous. Too often in the writer's experience has hot water brought about a speedy reaction in patients whose lives were almost despaired of. We are told that cases do not need flushing, that they do badly under it. Dr. Price believes that they do need flushing if they are desperate cases, and if they do badly, they do so not on account of the flushing, but because of the operation that preceded it. Next, we have a resort in packing. Gauze packing accurately applied to the bleeding or oozing surfaces, so that it can be removed without interfering with the otherwise completed operation, is of infinite value in hæmorrhage. It can be suffered to remain indefinitely almost, broadly speaking—at least, up to sixty or seventy hours, if absolutely clean and fresh, either salicylated or iodoformized. The drainage tube controls hæmorrhage. The drainage tube is currently spoken of as if it were an annex to pelvic surgery, easily dispensed with. The writer uses it almost without exception in adhesions. His results are better than those obtained without its use.

The plea of the paper was for absolutely exact, painstaking work, that shall leave nothing for regret, nothing to do over, nothing to explain, but shall stand out in the light of results as justifiable, scientific and perfect, when put beside methods that palliate without curing, and are no more a part of real surgery than is hypnotism refreshing sleep.

LAPAROTOMIES PERFORMED DURING THE PAST YEAR.

This was the title of a paper read by Dr. Thos. Opie, of Baltimore, Md.

The tabulated statement accompanying the paper embraced thirty-two abdominal sections made in the twelve months, beginning November 1, 1890, and ending October 31, 1891. The operations were performed consecutively as follows: Ovarian tumors, 6; chronic ovaritis, 7; fibroid tumors, 4; pyosalpinx, 5; retroflexion, with adhesions and dysmenorrhœa, 3; exploratory incisions, 3; extra uterine pregnancy, 1; abscess of ovary, 1; cyst of broad ligament, 1; cystic degeneration of ovary, 1.

Nine of these patients were operated on in the amphitheater before the whole class at the College of Physicians and Surgeons, the remainder, twenty-three, were operated on privately. Twenty-seven were white, and five were colored. The deaths were as follows: Oöphorectomy for pyosalpinx, 1; shock from ovariectomy, 1; oöphorectomy for acute mania, 1; and abdominal hysterectomy for fibro-cystic tumor, 1. Total, 4.

Stitch Abscess.—This complication occurred

nine times, a much larger number relatively than he had seen recorded heretofore. While no case proved disastrous, several were exceedingly annoying in delaying patients in hospital. They occur most frequently in cases where the drainage tube has been used. The early opening of abdominal dressings for any purpose favors their occurrence. When the dressings remained intact for seven days there seemed to be the greatest immunity from the stitch abscess.

Drainage was resorted to in but three cases during the year. Case 2, ovarian and dermoid cyst, had a drainage tube in five or six days, and the writer is convinced that it retarded the patient's convalescence. He is of the opinion that too much flushing is done; that it is but seldom called for. A plentiful supply of fine, properly prepared elephant-ear sponges will do away with flushing in most cases, and remove the necessity for drainage. They are efficient helps in keeping the abdomen free from infection.

(To be concluded.)

American Electro-Therapeutic Association.

The first congress of the American Electro-therapeutic Association, was held at Philadelphia, September, 24th, 1891, with the following officers:

President, G. Betton Massey, M.D., Philadelphia.

Vice-Presidents, William James Morton, M. D., Augustin H. Goelet, M.D., New York.

Secretary, William H. Walling, M.D., Philadelphia.

Treasurer, George H. Rohé, M.D., Baltimore.

Executive Council, Horatio R. Bigelow, M. D., Philadelphia; Franklin H. Martin, M.D., Chicago; William F. Hutchinson, M.D., Providence; Frederick Peterson, M.D., New York.

The first annual meeting of the American Electro-therapeutic Association was held in the College of Physicians, corner 13th and Locust streets, Philadelphia, September 24, 25, and 26, 1891.

The first session was called to order Thursday, September 24th, 3 P.M., with President Massey in the chair. After the meeting came to order, G. Betton Massey, M.D., Instructor in Electro-gynecology in the Philadelphia Polyclinic; Physician to the Howard Hospital; to the Dispensary for Women, etc., delivered an address on

A PLEA FOR THE ASSOCIATED CULTIVATION OF SPECIAL EXPERTNESS IN MEDICINE.

Gentlemen:—It is with much pleasure that I pronounce the American Electro-therapeutic Association an accomplished fact. Organized amidst many expressions of doubt on the part of occasional workers in electro-therapeutics, it has already met with a reception which ensures for it a

career of active usefulness in the near future, and has enrolled a membership with which it is an honor to be associated. It is of this infant organization that I wish to speak to you, of its reason for being and of its responsibilities, as an illustration of an important means of advancing the sum of human happiness by exalting the skill of practical workers in a certain field of medicine.

Among the special societies of the day none occupy the peculiar position of an electro-therapeutic association. None other is devoted to the study of a single therapeutic agent or has a membership embracing workers in so considerable a number of specialties. Narrow in one sense, it is in another sense nearly as broad as medicine itself, since there are but few departments of medical work unrepresented in our present programme.

But such an Association as this differs in a more important particular from other special societies. While composed like them of students of a certain subject, the members of this association are not exclusively devoted to the questions to be considered here. They are rather a company of special workers in diverse departments seeking greater expertness in the administration of a certain therapeutic force. That the progress of the healing art as a whole has made it incumbent on certain of its practitioners to devote special study to this one therapeutic force is a sign that medical art is partaking fully in the general advance of science, which demands the services of experts in every field. At the very inception of this association I therefore wish to lay stress upon a proper idea of its reason for existence. Let no one suppose that we are here to uphold or study any exclusive system of treating disease. We are here merely as experts and students desiring greater knowledge of a favorite art, and I trust that you will debar from membership any person who does not give adherence to medical knowledge as a whole, and make proper use of any and all agencies of value in the cure of the sick.

A necessity of the times, as evidenced in recent changes in medical education, is the enforcement of a broader culture among physicians. There is no doubt that this will tend to increase the membership of special scientific associations, but it must not be forgotten that these organizations themselves arise in a more peremptory assertion of the natural law of supply and demand. There is always a vast difference between the merely cultured man and the expert; the one delights us, but to the other we turn for the advancement of human knowledge and for real help in the crises of life. As the community increases in intelligence, this seeking after experts will doubtless become more pronounced in all departments of human service of man to man above the me-

chanical work of the common laborer, and we may well conclude that the healing art will partake fully in the benefits of this natural selection. A demand for experts creates a demand for expert training, an educational thoroughness that is well known to be impossible in our medical colleges at present. To meet this emergency there has fortunately grown up of late two agencies: the one, the post-graduate college, to teach ordinary skill; the other, the special society, which bears to yet unconquered disease the relation of a well-disciplined army to the borders of a hostile and unexplored country. Thoughtless men neglect both, but the wise see in such agencies the means of advancing personal knowledge of the practical needs of their work. It is to be hoped that their establishment will quicken an evolutionary process in our profession that will finally develop it into an ideal organization of skilled interdependent workers; where each member, profoundly cultured in the universal sciences of medicine, will yet confine his work to that branch in which he is skilled. Such a specialism in parts and members is nature's ever present pattern for our admonition and imitation. When such a time has arrived, the fortunate objects of our professional care will receive that highest skill to which they are in justice entitled, and which they rarely receive at the present moment.

In this hoped for Utopia of professional conscientiousness, skilfulness and modesty, I am sure it will be impossible to duplicate the position of a recent correspondent, whose apparently careful and exhaustive article on the electrical treatment of uterine fibroids in a recent journal led me to request him to discuss the subject at this meeting. He replied that he knew almost nothing about electro-therapeutics, a fact that I had already suspected. So remarkable an admission of ignorance from a person assuming the position of trying and judging causes one to wonder if he had been equally frank with the thirty or forty patients mentioned in the paper before undertaking their treatment. Well might we beg a modern addition to the ancient Hippocratic oath in which the medical men swore not to "cut for stone;" an addition that would compel the non-expert to forever refrain from assuming responsibilities for which his training has been insufficient, and that would have rendered impossible that recent crop of jacks-of-all-trades who have "tried electricity." Of all the enemies of scientific research in electro-therapeutics these are the worst. Not even the pure quacks do the harm of these Pharisees, who blunderingly attempt to use a remedy in private when their patients demand it, and publicly condemn it on the strength of such evidence. These mistaken attempts at medical omnipotence should be frowned upon as savoring of a crime toward both the patient and the remedy.

The organization of a national electro-therapeutic association crowns the full emancipation of this remedy from the thralldom of quackery. Neglected by the profession in the years that elapsed between the memorable medical experiments of Franklin in this city and the discovery of the dynamo, the marvelous triumphs of electrical engineers have at last aroused medical men to the need of discarding ideas, methods and appliances that preceded the electrical new world discovered some fifteen years ago. The assumption of new methods in electro-therapy has been extremely slow as compared with the industrial revolution which has already altered the face of civilized communities, but it is to be hoped that this body will be a powerful stimulus to the spread of scientific work in America.

Science is, however, but another name for truth, and in touching upon the objects of an association for the study of a force so well harnessed by natural law as electricity, it is evident that truth must ever be held as paramount in our discussions. Armed with laws that unlock the hidden power of this force over certain diseases, we are also equipped to demonstrate its utter uselessness in others by the application of an agnosticism that refuses to believe anything unless proven. But in clearing away the rubbish of unproven statements that make up so much of our archaic electro-therapeutic literature, we will by no means weed out the entire field of so-called medical empiricism. It is not alone in electro-therapy that the careless dicta of professional book writers has told us that such and such an agent is good for such and such a disease, without specifying the conditions that are necessary to save us from failure in actual practice. Read any classical work on general therapeutics that is ten years old, and see the blind empiricism from which all therapeutics have been evolved. There should be no nobler work for this Association than sifting the ancient claims for electricity, particularly in certain diseases of the nervous system, and establishing either their falsity or the conditions under which they are true. All remedial agencies are environed with limitations which vary with the dose used, the condition of the patient, etc., and this is particularly true of the one under consideration, which may in turn be a calmant, a stimulant, an absorbent, a solvent and a destructive agent. Here a hundred possible variations must be scanned to get the possible road to success, and hence this society is an eminently technical one. The broad question of the value of electricity in a certain disease should be subordinated here to exact data of the kind of current used, the dose, the duration and frequency of treatment, and the nature and position of the electrodes. All these should be specified before a claim is made that this agent is worthless in a given disease, since

a different combination of the same factors and conditions might have led to success. Similarly, the conditions giving rise to the successful treatment of a disease that should be specified with equal minuteness in order that others may find it possible to verify and duplicate our results.

It is for such work that the American Electro-therapeutic Association is needed, and badly needed. I do not decry the presentation of electrical papers to our various general and special societies, but it is in the nature of such presentations that they must assume the polemical attitude of enthusiastic endorsement or wholesale condemnation of general facts—must deal in glittering generalities—to be other than tedious to their audiences. Such papers do little to advance our knowledge of a special subject, and the speakers upon them are rarely capable of intelligently discussing the whys and wherefores of success and failure that I trust you will bring into prominence at these meetings.

Among the questions that demand this critical investigation, may be mentioned the whole subject of the use of electricity in organic nervous diseases and in the neuroses. We are here handicapped, of course, by a still imperfect knowledge of many pathological conditions underlying these diseases, yet I think it is even now possible to make a broad division of the electro-therapeutics of nervous diseases into two groups, the one acting by transferred physiological processes through the agency of the spinal and sympathetic systems, and the other acting by virtue of a direct passage of lines of flow through, or by a polarization of, the primary or secondary seats of the disease. The indirect method is, unfortunately, the most common, since we are restricted to it frequently by the deep situations of the diseased areas, and in its various applications we are limited in progress by the limitations of these physiological carriers of our remedy. We are here in much the same position as in prescribing drugs, whose action is generally limited by the circuitous routes of absorption and circulation. It is doubtless in the method of direct action that electricity will yet make its greatest advances in the treatment of nervous diseases; a method which involves the possibility of concentrating a sufficient density of lines of force through a diseased area to accomplish an alteration in its nutritive condition. This is yet an almost virgin field in neurology, depending somewhat upon improved methods of conducting efficient currents through the dermic surface, and in estimating the possible future value of strong currents thus scientifically conducted to the actual seats of disease, I can conceive of but one organic basis of disease as absolutely and at all times unpromising and resistant, namely: that due to living germs.

Of the work before you in considering the value of electricity in gynecology, I need not

speaking at length. This is regarded as a most important question in every gynecological society in the world, and while we are fully justified in considering its relative value as compared with other means, we will have a greater opportunity to discuss the many technical questions that belong to the subject. Here, indeed, is material for a society alone. The exact methods used by men of large experience in the various diseases of women are living questions that come home with force to any one who essays this work. Such things are rarely well shown in books, because of the changing extent of our yet imperfect knowledge. Owing to the many possibilities of direct treatment in gynecology, we have nevertheless already accumulated a most respectable series of exact therapeutic facts, with many useful rules deducible from them, and in the great activity now characterizing this branch of electro-therapeutics, an almost daily advance in our knowledge is inevitable. It is in this department of diseases of women, that electricity as a remedy has encountered its first real and bitter opposition from non-users in the profession, but we should remember that here its greatest value as a curative agent is becoming conspicuous, for "the blood of the martyrs is the seed of the faith." To its good work of restoring health and function by combating diseased processes, has been added the labor of combating unwise surgery, that, in a laudable effort to perfect a useful technique, has sacrificed thousands of patients and parts of patients on the altar of harsh experiment.

Among other branches of the work, great interest attaches also to the electro-therapeutics of visceral and circulatory diseases, of dermatology, of strictured canals and orifices, and of the nasopharynx. Each of these questions will be infinitely better understood when discussed by experts, and cannot fail to be placed on a higher plane of scientific exactitude by each one of our annual gatherings.

As important accessories to these advancements in our ability to cure and control disease, certain questions of detail common to all this work demand our attention. This Association should take action on the important matter of securing a uniform and reliable calibration of our milli-ampère meters. Many of the instruments supplied to the profession are improperly graduated, and others soon fail to read correctly through imperfect construction. This is surely a matter of greater importance than the correctness of the scales used in trade, over which the State wisely maintains a supervision. In the absence of Government assistance in verifying our instruments, some practicable substitute should be devised. Our Faradic batteries are also yet far from perfect, besides being devoid of intelligent means of graduation, and I trust that you will take early

steps to bring this somewhat old-fashioned instrument up to the high character demanded by modern work.

Such, in briefest language, are some of the reasons why special workers should meet in occasional conclave. To the unfortunate sufferers from the affections coming under our care, this meeting is fraught with high consequences. Unless we can go back to them with an added power over disease, our coming here is bereft of its highest value, for in the presence of human suffering, we can recognize utility alone as our measure of results.

Dr. Bigelow, Philadelphia: I think some resolution should be made on the President's able address, and I move that a committee be appointed to take action thereon and report at our opening session to-morrow, and that the President be requested to appoint three gentlemen for that purpose.

Motion seconded and carried, and Drs. Bigelow, Goelet and Morton appointed.

(To be continued.)

STITES' TEST FOR CARCINOMA.—On October 17th, at the surgical clinic, I removed for atrophic scirrhus the right breast of a female, aged sixty-one. In the presence of the class the tumor was immediately subjected by Dr. W. M. L. Coplin to the test of Mr. H. J. Stites, of Edinburgh. The method of examination was that furnished me by Professor Chiene, of Edinburgh, which I give in his own words:

1. Excise the mamma.
2. Wash thoroughly in water to remove blood.
3. Place in a 5 per cent. solution of nitric acid (B. P.) for ten minutes.
4. Wash in cold water for five minutes.

By the time these procedures are executed the axilla is cleaned out and the vessels tied. The mamma is now examined; the carcinomatous structure appears a dull white, like the eye of a boiled fish, the healthy tissue translucent. When any such reaction is seen additional tissue should be removed at the corresponding point.

In removing the carcinomatous breast, Professor Chiene directs that its relations to the circumferential tissues should be marked by the knife, so that after the test has been applied to the mass excised the situation of any outlying, unremoved diseased areas can be fixed.

In the case operated upon the foregoing directions were carefully followed by Dr. Coplin, who demonstrated to the class that the infected tissue became of the characteristic "dull white," resembling egg-albumen, while the uninfected tissue appeared translucent and gelatinoid, affording a striking contrast to the carcinomatous structures. The reaction in the axillary glands seemed even more marked than that in the breast; it therefore would, perhaps, be well always to retain one gland for comparison with those treated with the acid.

The test described by the distinguished Scottish surgeon as devised by his assistant, Mr. Stites, appears to be a most perfect one. It is to be hoped that future trial will show that it can be depended upon, and that it can really be accepted as a gauge of the thoroughness and sufficiency of removal of carcinomata, not only of the mamma, but also of other parts.—John H. Brinton, M.D., in *Med. News*.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,

No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, NOVEMBER 28, 1891.

DIET IN FEVER.

The dietetic management of the febrile state is always a matter of interest, and an extract in *L'Union Médicale* from a work by MAUQUAT, soon to appear, covers the ground so logically that we have thought it desirable to review it for the benefit of our readers.

During an acute fever, the appetite is usually diminished; the mouth is dry from the diminished salivary secretion, and this latter feature is an index to the secretions generally throughout the alimentary tract. In the stomach the gastric juice is secreted not only in diminished quantity, but is changed in quality, the hydrochloric acid being much reduced. The frequent craving of febrile patients for acids is thus explained, and although we do not have to resort to the means of the wise old doctor who, before the days of the clinical thermometer, found that a child was feverish by asking which it would have, an orange or some candy, and finding that it preferred the orange—still the lesson is not useless to-day. The pepsin, on the other hand, is not diminished, at least, enough is always present to carry on the functions of gastric digestion if the acid be supplied. In the duodenum it is found that the pancreatic and biliary secretions are diminished, and that the digestion of fats is thereby rendered nearly negative. In addition, the absorptive func-

tions of the alimentary canal are decidedly below normal.

The febrile state results in the production of an increased amount of tissue change, with corresponding increase of poisonous waste products, while the exciting cause of the fever also adds to the poisons elaborated and calling for elimination. In typhoid fever, the blood contains 7 to 9 per cent. of extractives, while normally it should contain 4 per cent., according to ROBIN.

A low diet protects the impaired digestive tract, is a powerful means of lowering temperature, favors absorption of liquid from the tissues, thus relieving congestion, and prevents the admission to the circulation of alimentary poisons; but, on the other hand, it prevents tissue repair, and allows the body to waste. It therefore becomes a cause of weakness, and prolongs convalescence.

Food capable of proper digestion and assimilation prevents an excessive bodily wasting, and furnishes strength to the patient to combat the disease, but overfeeding is disastrous. It introduces into the alimentary canal material which can be neither digested nor absorbed, and which acts as a foreign body, exciting at times vomiting and diarrhœa. It frequently causes an elevation of temperature and an increase in the pulse rate, favors a tendency to exudations, and in the case of albuminous food, often gives rise to poisons which, when absorbed, either produce symptoms or increase the burdens of the emunctories.

Proper feeding in fevers may therefore be said to consist in giving to the patient such articles of food as can be digested and absorbed, in quantities that can be completely managed by the digestive agencies, avoiding substances which, for mechanical or chemical reasons, might be contra-indicated. Take the medium view advocated by Hippocrates, who observed that it was as bad to feed too little as to feed too much.

Eggs as a food in fever are distinctly contra-indicated. No class of albuminous foods requires so much hydrochloric acid for digestion, and this is the element of the gastric juice which is wanting. The use of this acid after feeding seems insufficient. Meats fall into the same category, and are hardly ever available as foods unless administered in small quantities, very finely subdivided. The diminished motility of the stomach, which favors the retention in that

organ of food, directly favors the decomposition of meat.

Various views have been held regarding milk. G. SÉE says that it is badly digested, and DUJARDIN-BEAUMETZ believes that its principle utility is to be found in the water and salts which it contains. It is, nevertheless, a food which is generally relished, and which certainly is most useful in fevers. If hydrochloric acid be administered with it, there can be but little doubt that it is fully digested.

Bouillon is often decried because of its lack of nutritive value. As ordinarily made, it does not contain much albumin, but it is rich in salts. According to A. ROBIN, there is in typhoid fever a true mineral inanition, and he regards bouillon as an excellent means of supplying the deficiency.

It is more than improbable that the organism can utilize mineral water brought to it in this shape, and it seems certain that these very salts hinder the antitoxic action of the liver. Beef tea should therefore rather be regarded as a palatable means of administering water. Although gelatine alone is of but slight nutritive value, yet it is usually agreeable to the fever patient, and when administered with some form of albuminous food, its nutritive value is markedly increased. Starches are well digested by fever patients, and, together with sugars, should constitute an important part of their diet. These latter substances are best administered in drinks. Drinks, particularly of pure water, lemonade, diluted wine, aerated waters, rice and barley water, are of the greatest value to these patients. Fats should not be given, because of the failure of the pancreatic juice. Cream, however, is an exception, and, as found in milk, is well borne. This outline may serve well as a general guide for feeding in fevers, always to be modified by the particular conditions present in any special febrile process.

THE AMBULANCE SERVICE OF GENERAL HOSPITALS IN CITIES: "THE LITTLE WARD ON WHEELS."

One of the modern improvements of hospitals is the ambulance—inclusive of the bright young surgeon. If we mistake not, twenty years ago there were not in the country more hospital wagons than could be counted on the fingers of one hand, while

now there are in some cities eight or ten thoroughly equipped vehicles. The last report of the superintendent of the Johns Hopkins Hospital alludes to the want, felt at that institution and in the city of Baltimore, of some adequate means of transit for its patients. DR. HURD writes as follows: "An ambulance is desirable and would serve a most useful purpose. There is at present no ambulance system in Baltimore and accident cases and cases of severe disease are forced to rely upon the police patrol wagon, which does not furnish any adequate shelter from the sun or storm, or good facilities for the transportation of the sick and wounded. The excellent ambulance service which exists in New York should be adopted in this city. Many applications are made for the services of such a vehicle, and it is to be regretted that the hospital does not possess one."

In nearly all our cities where any two institutions come into friendly competition for surgical and police practice the ambulance becomes an absolute necessity, otherwise the institution that is most centrally located will outstrip the others, if the latter do not take steps to provide the "little ward on wheels." And further, when two such conveyances come into competition, it is most interesting to observe how the service brightens up, and picks up new points and appliances—all of which redound to the better care of the sick and wounded. Of the character of the young ambulance surgeon in a certain city of our acquaintance—where the appointments are made as the outcome of competitive examination—we cannot forbear to quote the opinion of a judge, of high repute in criminal and violent cases, that these young men are almost always good witnesses, intelligent, clear-headed and courteous, and make a deep impression upon the jury as well as on the jurists. The public or court duties of the meritorious surgeon has, in this way, proved a useful introduction to valuable connections. Ordinarily there is a warm enthusiasm and *esprit de corps* on the part of the surgeons which serves the patient's interests during many a critical moment, besides yielding a various and vivid experience very different from that which awaits the budding practitioner who has no public functions or advantages. In some cases the ambulance surgeon is the "junior house" and is required to give six months to the ward-work of his hospital be-

fore he goes out on the wagon to act upon his own responsibility—a rule which has been found to shield the young surgeon against allegations of “total inexperience” and the like. In some of our cities, the volume of business performed by the ambulance service will exceed an average of a thousand cases per annum to each wagon, or over three calls per diem. In the case of a large conflagration or other great casualty, a great amount of labor falls on the ambulances; and they become the means of relieving a great deal of suffering and of preventing much injurious delay. Unauthorized demands upon the service, or “fake calls” as they are sometimes termed, are a detriment to its earlier periods. They tend to diminish, however, as the service matures, especially if harmonious relations with the police are maintained and if an efficient signal system is supplied.

The question of the annual cost of an ambulance is an important one to all hospital authorities who are canvassing the subject of its introduction. The cost of the original plant may vary greatly in different localities, for some institutions are so constructed as to have no space to spare for ambulance purposes, while others can be adapted thereto quite inexpensively. From some inquiries recently made, we judge that the average outlay for a plant, made *de novo*, may be stated at one thousand dollars, while the running expenses per month need not exceed one hundred dollars per month during the first year. This pre-supposes that no salary is paid to the house-surgeon who acts as ambulance surgeon. It would be a better plan to increase that monthly amount by thirty or forty dollars, to be set aside as a partial recognition or *courrecour* to the young surgeon. The hospital should supply uniforms to all who appear in public in connection with the ambulance. Numerous considerations—nearly all of them referable to the public good—make this step advisable, although the expense account is materially increased thereby. In conclusion, the American system of hospital ambulances, as the foreign journals generally designate the system, as it has gradually grown up in this country, may now be seen in some European cities, and so far as we have heard, no hospital, either abroad or at home, that has once undertaken this line of service, has ever been content to be deprived of it. The ambulance is, in its

essence and development, a humane and life-saving institution, almost as much so as the hospital itself; it is a kind of wheeled extension of the examination ward. It is in fact permissible to call it “the little ward on wheels.”

ACTING ASSISTANT SURGEON U. S. A.

We are in receipt of an attractive little volume, having a title as “Records of the Association of Acting Assistant Surgeons U. S. A.,” which gives an insight into the reasons for such an organization, with a brief sketch of those who are at present identified with it.

The purposes of the Society are mainly to work for a proper recognition of the corps, on the part of the government.

In the first place, it was very unfortunate that the title of *Acting Assistant Surgeon* was given this corps, as the name carries with it a feeling that it is applied to a substitute, and substitutes among the soldiers during the war were odious and not held in high estimation by any one. These Acting Assistant Surgeons should have been given an actual rank, as they were called upon to perform all the varied services of a commissioned officer, and we are ready to bear testimony to the efficiency, professional skill, and arduous labors of a goodly number of these physicians who were in the service during the late war.

Inasmuch as the government finds it necessary to continue the service of fifty Acting Assistant Surgeons, justice demands that the offensive title of *Acting* should be dropped and that of Assistant Surgeon of the second grade established. The officers of the grade to rank as Second Lieutenant, and where the officer is below the proper age, he should be allowed the privilege of examination for promotion.

In this connection we suggest to the officers of the government in both the Army, Navy and Marine-Hospital Service, the eminent propriety of holding examinations at stated intervals in all the principal cities of the Nation. This would have a most favorable influence in popularizing the government service. We believe the Navy is always short of medical officers, and perhaps this may be said of the other departments. The convening of a board of examiners in Chicago, Detroit, Cincinnati, Louisville, St. Louis or New

Orleans would have a good effect upon the National service and also upon the medical profession in those cities and the country tributary to them.

The Surgeon-General of the Army and Secretary of War are loudly called upon to take such action as may be necessary to bring about needed improvement in the rank and title of those who are recognized as honorable men and skillful medical officers, but who are serving our country under an unjust and odious designation.

STITES' SURGICAL CRITERION FOR CANCER.

DR. JOHN H. BRINTON has put into practice at his surgical clinic at the Jefferson Medical College a new test for cancer, proposed by MR. H. J. STITES, of Edinburgh. The method, as given by DR. BRINTON, in the *Medical News*, October 31, is that which was furnished him by DR. JOHN CHIENE, of the Royal Infirmary of Edinburgh, and reads as follows:

- "1. Excise the mamma.
2. Wash thoroughly in water to remove blood.
3. Place in a 5 per cent. solution of nitric acid (B. P.) for ten minutes.
4. Wash in cold water for five minutes.

By the time these procedures are executed the axilla is cleaned out and the vessels tied. The mamma is now examined; the carcinomatous structure appears a dull white, like the eye of a boiled fish, the healthy tissue translucent. When any such reaction is seen additional tissue should be removed at the corresponding point.

In removing the carcinomatous breast, PROFESSOR CHIENE directs that its relations to the circumferential tissues should be marked by the knife, so that after the test has been applied to the mass excised the situation of any outlying, unremoved diseased areas can be fixed."

The above description, although applied in this instance specifically to mammary cancer, need not be limited to that affection, but may be used for other diseased glandular structures. DR. BRINTON'S case, operated upon October 17, was, however, a mammary cancer, and the demonstration of the test before the class was made by DR. W. M. COPLIN, while the surgeon proceeded with the removal of the diseased structures. The reaction in regard to the infected axillary glands was more distinctly noted than in the breast tissues; it would, therefore, be proper always to retain one of the excised glands, without the treatment by the acid, for purposes of comparison. This procedure or test devised by MR.

STITES, who is spoken of as an assistant of the distinguished Scottish professor of surgery, "appears to be a most perfect one," as DR. BRINTON says. It is worthy of careful trial in order to ascertain if it can be relied upon under differing conditions as regards the sight and nature of the malignant growth. It will be no small gain to surgery if this test can really be accepted as a criterion or gauge of the thoroughness and sufficiency of the operative steps for the ablation of cancerous masses, not only of the mamma, but also of other parts.

DOMESTIC CORRESPONDENCE.

Deming (N. M.) as a Health Resort.

As regards Deming for a health resort for people coming from the East, affected with pulmonary or bronchial troubles, we would say:

Deming is situated on a plain, surrounded by mountains, comprising an area of about 50 miles square. This is at an elevation of about 4,500 feet above the level of the sea. The temperature on this plain is always mild, never going below the freezing point in day time during mid-winter, while the heat during the summer never becomes extreme. The rainfall is exceedingly slight, limited principally to the months of July, August and September, while the air during the rest of the year is comparatively free from moisture.

The water-supply is received from the Black Range, which is a spur of the Rocky Mountains. The water is the purest in the territory, being filtered through a stratum of sand for a distance of 25 miles before reaching town; thereby freeing it from all impurities, before it is used.

With these facts in view, we would state as follows: All patients affected with pulmonary tuberculosis coming from the East to this country, before the disease has progressed too far, who will take the proper amount of exercise in the open air, live on a healthy diet, have nine chances out of ten for their ultimate recovery, as proven by personal experience during nine years of practice in this part of the territory.

Patients affected with chronic bronchitis find it advisable to remain from July to January or February, when the winds commence to blow, experience having proven, that during that time of the year they make the most rapid and satisfactory progress; but even in the windy season seldom have really obstinate cases of bronchial troubles come under my observation.

With the railroad facilities, which this place enjoys, the pure, dry atmosphere, the unusually good water, the equable climate, which permits people to stay out of their dwelling at all hours of the day the year round, we would recommend Deming most highly as a suitable point for establishing a health resort.

J. W. WILLIAMS, M.D.

Deming, New Mexico.

THE *Sanitary Record*, of London, owing to the financial difficulties of Messrs. W. H. Allen & Co., the publishers, has passed into other hands, and is no longer edited by Miss Hart.

BOOK REVIEWS.

MEDICAL COMMUNICATIONS OF THE MASSACHUSETTS MEDICAL SOCIETY. Part II of Volume XV. 1891. Boston: David Clapp & Son.

This is a notable issue of a long and valuable series. Very few pages are allowed to run to weeds in these "Communications." We desire, in the first place, briefly to draw attention to the paper entitled the Shattuck Lecture, by Dr. Edward Cowles, of Somerville. Its subject is "Neurasthenia and its Mental Symptoms." This essay is a long one, comprising, as it does, over a hundred closely printed pages, but it is none too long, as being the best résumé of the subject that has appeared in ten years. Dr. Cowles is the medical superintendent of the McLean Asylum, or branch for the insane of the Massachusetts General Hospital, and appropriately addresses himself to some of the parallel workings of pathological fatigue and certain of the forms of insanity which have their etiology in common, namely, in nervous enfeeblement. The fundamental idea of the writer is that there is a moderate auto-intoxication even in normal fatigue, from or after the discharge of energy, by the toxic products of exercise, always formed in both nervous and muscular structures. These toxic elements tend to accumulate in the blood and tissues of the neurasthenic patient, and manifest their ill-effects by a local or general inanition and auto-intoxication greater in degree than that which marks the advent of a temporary and repairable weakness of the nervous tissues, such, for example, as is seen in the evening tire of an active man. There are visible changes in nerve cells consequent upon normal fatigue, thus supporting the hypothesis and argument of those who teach that there is a molecular and chemical alteration in pathological fatigue, manifested as a condition of exhausted nutrition. The question of the influence of autogenous toxic substances is approximately answered by the writer in the affirmative from the analogies which are presented by our rapidly growing knowledge of the action of bacteria in the body. Just as ptomaines are noxious to the microörganisms producing them, so are normal cells injured when the products of their own activity accumulate about them. The following is Dr. Cowles' systematic definition of the disease he is considering: "Neurasthenia is a morbid condition of the nervous system, and its underlying characteristics are excessive weakness and irritability or languor, with mental depression and weakened attention." He dwells with special emphasis on the position that the mental symptoms of pathological fatigue are entirely harmonious with the physical phenomena of neurasthenia, and that these, as far as they can go, are in their turn in agreement with the march of events in melancholia. And he adds that neurasthenia may be regarded as the initial term of many another nervous derangement having wide and varied causations. Dr. Cowles' remarks upon two of the prominent specially neurasthenic conditions are interesting. The first of these is the state of "morning tire," or "morning depression." This is sometimes termed the "morning misery;" but the essential element is tire, where the patient awakes in the early morning and is unrefreshed by sleep. The second is that paradox of neurasthenics which is known as the *anæsthesia of the sense of fatigue*, a descent towards the depths of nervous prostration which indicates the waning of sensory power. The sense of fatigue—a natural sensation—ceases to guide the patient. He is conscious of both mental and physical incapacity, but he cannot agree with those who warn him against over-exertion.

These patients are both self-deceiving and misleading to others: these are they who "travel on their nerves," and who are sent abroad to recruit by travel and a change of scene, when they have only the illusory appearance of the strength to undertake it. So, too, should be remarked the converse of this proposition, when these invalids are in the process of restoration to health; they must of necessity come back to "the sense of feeling," as this anæsthetic state departs, and what is the result? They say they feel worse, when they are getting stronger; they alarm their friends, perhaps mislead their medical advisers, but the process is nevertheless an appropriate and almost inevitable step along the upward path to convalescence. So that one might be pardoned who would say of neurasthenia: Its name is Legion and the truth is not in it. There are not a few points in the study of the downward and upward course of this affection where-at the alienist has the advantage—both in diagnosis, prognosis and in treatment—over the average practitioner. These patients are sometimes said to be supersensitive of conscience and are known to be self-reproachful because they accomplish so little. They especially feel the burden of household duties, and the fault is not infrequently ascribed to the *res angusta domi*, but in this view of the case, these conditions just named and all their congeners are contributive and non-essential. They are environments, extrinsic to the true trouble.

Sometimes these patients display their paradoxical abilities by extraordinary "spurts" of apparent endurance, but they have all to be "paid for" with a repentance and recoil that are quite sure to take the form of a renewed and intensified self-reproach, with all its harmful consequences.

Concerning "worry," Dr. Cowles says but little, but he does advise the breaking up of painful association, on the ground that a change from all the usual surroundings often does great good. Even homesickness may become an advantage—since it is a different and more natural form of "worry," that works to advantage when it displaces a morbid worriment. As to insomnia in these patients, the elimination of waste products is logically a prime element in the treatment. Sleep should be promoted by the use of as little narcotic drugs as possible. The tendencies of the latter are to spoil the appetite and to produce secondary morbid effects; a forced quietude of the brain cells may not promote their rest and nutrition. A drug having a disagreeable taste is the least harmful, as for example the paraldehyde mixture of Dr. Folsom of Boston, which consists of a few minims of that drug in a drachm of chloroform water, and this can be repeated a number of times; sulfonal is at present to be placed among the safest of the hypnotics. Warm baths and feeding at night answer very well in many cases.

In addition to this paper of Dr. Cowles, there is another by Dr. F. H. Williams on "Non-nutrition in Acute Disease." It is a practically conducted study, not altogether foreign to the subject we have been considering, and we will be glad if we shall be enabled to repeat some of its salient features in a future issue. There are also surgical and obstetrical contributions of more than ordinary interest, which we cannot even name.

MISCELLANY.

MITCHELL DISTRICT MEDICAL SOCIETY.—At the meeting of the Mitchell District Medical Society in Columbus, Ind., December 17, and 18, 1891, the following papers will be presented.

First day.—"Is the Treatment of Phthisis Pulmonalis a Success?" Dr. S. A. Ariden, Bedford.

"The Respiratory Complications of the Disease called La Grippe," Dr. Theodore Potter, Indianapolis.

"The Use of Alcohol in the Practice of Medicine," Dr. Homer J. Hall, Franklin.

"Tetanus, with Report of Cases," Dr. John D. Simpson, Bedford.

"Intubation of the Larynx," Dr. Joseph Eichberg, Cincinnati.

"Intubation in Diphtheria," Dr. P. R. Taylor, Louisville.

"The Enlarged Tonsil," Dr. Dudley S. Reynolds, Louisville.

"Surgical Treatment for the Relief of Nasal and Nasopharyngeal Reflexes," Dr. L. C. Cline, Indianapolis.

"Correct Pronunciation of Medical Terms," Dr. M. N. Elrod, Hartsville.

Evening Session.—Public Address, Dr. G. C. Smythe, Greencastle.

Second Day.—"The Necessity of Surgical Knowledge in General Practice," Dr. J. R. Jenkins, Shelbyville.

"Posterior Spinal Sclerosis," Dr. H. M. Lash, Indianapolis.

"The Pathology of Nervous Exhaustion," Dr. A. B. Richardson, Cincinnati.

"Abdominal Section, with Report of Cases," Dr. Wm. H. Wathen, Louisville.

"Recurrent Pelvic Inflammation," Dr. L. H. Dunning, Indianapolis.

"Hæmorrhage at or near the Menopause," Dr. C. A. L. Reed, Cincinnati.

"Antiseptics in Rectal Surgery," Dr. Jos. M. Mathews, Louisville.

"Reflex Disturbances from Rectal Disease," Dr. J. M. Cook, Indianapolis.

"Skin Grafting," Dr. A. M. Owen, Evansville, Ind.

"Remarks on the Treatment of Urethral Stricture in the Male," Dr. W. N. Wishard, Indianapolis.

"The Radical Treatment of Inguinal Hernia," Dr. A. J. Banker, Columbus.

Hotel rates, \$1.50 per day; reduced rates on railroads entering Columbus.

Columbus is one of the best towns in Indiana, and the local profession will spare no pains to make this meeting a success in every way.

ELIJAH S. ELDER, A.M.M.D., Indianapolis, President.

GEO. W. BURTON, M.D., Mitchell, Secretary.

Chairman of Committee of Arrangements,

GEO. T. MCCOY, M.D., Columbus, Ind.

THE MEDICAL SOCIETY OF THE MISSOURI VALLEY.—

The next meeting of the Medical Society of the Missouri Valley will convene in Lincoln, Neb., Thursday evening, December 17, and continue in session on the 18th. Physicians reading papers or presenting cases at that meeting will send the undersigned their titles before December 1, so they can appear upon the programme, which will be mailed at that date. F. S. THOMAS, Sec'y.

Grand Hotel Annex, Council Bluffs, Ia., Nov. 15, 1891.

NORTH CENTRAL ILLINOIS MEDICAL ASSOCIATION.—

The eighteenth annual meeting of the North Central Illinois Medical Association will be held in the City Hall, Streator, Illinois, on Tuesday and Wednesday, December 1 and 2, 1891.

GENERAL PROGRAM.

Ergot, James Tweddle, M.D., Washburn. Discussion, C. E. Davis, M.D., Peoria, E. T. Goble, M.D., Earlville.

Treatment of Miscarriage, W. A. Mansfield, M.D., Metamora. Discussion, A. H. Kinnear, M.D., Henry, B. L. Bonar, M.D., Streator.

My last One Hundred Obstetrical Cases, G. C. Lewis, M.D., Fairbury. Discussion, Geo. Ryon, M.D., Amboy, T. C. Fenton, M.D., Streator.

Hydrogen Gas Inflation with Negative Results in

Stomach Perforation, E. W. Weiss, M.D., Ottawa. Discussion, E. P. Cook, M.D., Mendota, G. A. Zeller, M.D., Peoria.

Neoplasms of the Post-Nasal Space, J. H. Coulter, M.D., Chicago. Discussion, I. H. Reeder, M.D., Lacon, S. V. Hoopman, M.D., Roanoke.

Clinical Cases—Nasal Polypus and Gastric Catarrh, L. G. Thompson, M.D., Lacon. Discussion, J. C. Hatheway, M.D., Ottawa, C. D. Chalfant, M.D., Streator.

The Use and Abuse of Alcohol, W. L. Rabe, M.D., Dwight. Discussion, J. H. Braffet, M.D., Paw Paw, A. N. Richardson, M.D., Ohio.

Sciatica, C. C. Hunt, M.D., Dixon. Discussion, G. L. Burns, M.D., LaSalle, A. E. Owens, M.D., Dover.

Bright's Disease, H. Ziesing, M.D., Peru. Discussion, J. W. Edwards, M.D., Mendota, G. W. Bronson, M.D., Streator.

Prolapse of Vagina and Bladder in a Child Twelve Days Old, B. S. Roseberry, M.D., Lacon. Discussion, A. E. Palmer, M.D., Morris, W. L. Smith, M.D., Streator.

Has Typhoid Fever a Differential Pathognomonic Symptom? J. Stout, M.D., Ottawa. Discussion, J. S. Whitmire, M.D., Metamora, J. W. Pettit, M.D., Sheridan.

General Country Practice, W. G. Putney, M.D., Prairie Centre. Discussion, F. C. Robinson, M.D., Wyandot, F. M. Pendleton, M.D., Magnolia.

Special Program for Tuesday evening, December 1, 1891. Annual address of the President, by J. A. Freeman, M.D., Millington. Subject, The General Practitioner.

General address by W. T. Belfield, M.D., Chicago. Subject, Some Diseases of the Urinary Organs.

The first session will begin on Tuesday, December 1, at 10:30 A.M.

Members assigned to open the discussion of papers will be limited to ten minutes and volunteer remarks of others to five minutes.

Physicians eligible to membership are invited to unite with this Association and contribute papers, clinical reports or professional experience, and engage in the discussion of papers presented at its meetings.

Members of the dental profession and others interested in the study or progress of medicine and surgery or allied subjects are at all times cordially welcomed in attendance upon its sessions.

Copies of by-laws and membership blanks forwarded on application to the secretary.

J. A. FREEMAN, M.D., President.

WM. O. ENSIGN, M.D., Secretary.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from November 14, 1891, to November 20, 1891.

Capt. Edwin G. Gardner, Asst. Surgeon U. S. A., is relieved from further duty as attending surgeon and examiner of recruits in New York City.

Asst. Surgeon Benjamin L. Ten Eyck is granted leave of absence for one month, to take effect about the 15th inst.

Capt. Charles Richard, Asst. Surgeon U. S. A., is granted leave of absence for one month.

First Lieut. Charles F. Kieffer, Asst. Surgeon (recently appointed), is assigned to duty at Ft. Sheridan, Ill.

First Lieut. Frank T. Meriwether, Asst. Surgeon (recently appointed), is assigned to duty at Ft. Adams, R. I.

Capt. Edgar A. Mearns, Asst. Surgeon, is relieved from duty at Ft. Snelling, Minn., and assigned to duty at Ft. Mackinac, Mich.

First Lieut. Charles Willcox, Asst. Surgeon, is relieved from duty at Ft. Bowie, Ariz., and assigned to duty at Ft. Gaston, Cal.

First Lieut. Henry C. Fisher, Asst. Surgeon (recently appointed), ordered to Ft. Riley, Kan., for duty.

First Lieut. Henry A. Shaw, Asst. Surgeon (recently appointed), ordered to Ft. McKinney, Wyo., for duty.

First Lieut. Samuel R. Dunlop, Asst. Surgeon (recently appointed), ordered to Ft. Sill, Oklahoma, for duty.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending November 21, 1891.

Medical Inspector Theodor Woolverton, placed on the Retired List November 13, 1891.

Asst. Surgeon P. H. Bryant, detached from coast survey str. "Gedney," and wait orders.

Surgeon W. H. Jones, ordered to examination preliminary to promotion.

ORIGINAL ARTICLES.

PERSONAL HYGIENE IN SCHOOLS.¹

REPORT OF W. L. SCHENCK, A.M., M.D., FROM
THE COMMITTEE ON SCHOOL HY-
GIENE, A. M. A.

*Read before the Section of State Medicine, at the Forty-second An-
nual Meeting of the American Medical Association,
at Washington, D. C., May, 1891.*

BY W. L. SCHENCK, M.D.,
OF TOPEKA, KANSAS.

*Physical Training—Study—Time and Amount—Recess
and Vacation—Instruction in Hygiene—By Whom
Taught—How Taught—Prevention of Contagious
Disease.*

"Train up a child in the way he should go,
and when he is old he will not depart from it."
The converse of this proposition of "the wise
man" is equally true. The teachers of a nation
forge its future. Its schools are their work-
shops. No vocation is so freighted with respon-
sibility as that which moulds the coming age.

During the formative period of their lives, the
children of America are in her public schools,
and they have far more to do with their physi-
cal, mental and moral forces than either the
home or the church. We say physical, as well
as mental and moral, for while teachers are wont
to consider their business with the mind and
soul, there is no such thing as mental and moral
education *per se*; no such thing as physical edu-
cation *per se*. The development and strength of
the physical and spiritual are constantly interde-
pendent. The evolution of higher types of
human life requires co-education.

As the intellectual and moral man collects,
correlates and manifests all its knowledge through
the instrumentality of the body, and as its tan-
gible relations with this world are dissolved by
the death of the body, we cannot emphasize too
strongly the importance of a personal hygiene
that will secure the full, round development of
body, mind and soul.

Personal hygiene during school life embraces
physical development and physical subjection to
the intellectual and moral forces. The body

must be trained to the requirements of the spir-
itual life, whose healthful evolution can only
obtain through the instrumentality of a healthy
body. Whatever the possibilities of an immor-
tal soul, while connected with the body, they lie
largely in its health and strength, and as each
added year gives larger knowledge and greater
power to the mind, the interests of both the in-
dividual and the State demand that during school
life there shall be imparted such knowledge of
hygienic laws, and such habitual obedience, as
will tend to secure a life of threescore years and
ten, or, as modern science has demonstrated that
animal life is five times the length of its devel-
opment period, of fivescore years.

While physical training must take into con-
sideration all the organs and tissues of a most
complex physical structure, as well as their sur-
roundings, each individual has a heredity and
temperament, environments and an idiosyncrasy
that require personal consideration. One organ
must not be developed at the expense of another,
and that which is weak must be strengthened,
for the whole is never stronger than its weakest
part. The child must be developed into the
semblance of "the deacon's one-horse shay,"

That was built in such a wonderful way,
It ran a hundred years to a day.

For the deacon said :

There is always *somewhere* a weakest spot,
And that's the reason, beyond a doubt,
That a chaise *breaks down*, but doesn't *wear out*.

This development can only be attained through
the formation of habits that will control the pas-
sions, emotions, appetites and desires, and by
such properly regulated exercise as will secure
the regular generation and distribution of ner-
vous force, the free use of the lungs, and a cir-
culatory action that will carry the blood to every
capillary, that will excite normal secretion and
excretion, give a sense of added strength, in-
itself invigorating, and insure peaceful and re-
freshing sleep, always avoiding such violent
effort as tends to local injury and premature
death.

In all exercise, gladness is an essential ele-
ment. Joy, faith, hope, are the stimulants that
make exercise, whether physical, mental or mor-
al, healthful. All exercise, especially in child-

¹ This paper should have been published with other papers of
the Section on State Medicine, but was not received by the editor
of THE JOURNAL until Nov. 19, 1891.

hood, must be alternated with frequent intervals of rest. If we watch the gambols of young animals, we note constant change, but such use of every muscle as secures harmonious and healthful development. During school life, perhaps, there is nothing better than Betts' method of physical culture, in which the whole school should engage in concert, at least once during each morning and afternoon session. This exercise, properly conducted, yields the joy of the dance, calls into play all the muscles of the body, brings them into subjection to the will of the individual, and subjects the individual will to that of the instructor. During each session there should be a few moments of rest from study given to quiet social intercourse.

We have seen in the Topeka (Kansas) high school, under the charge of Prof. H. G. Lorimer, three hundred pupils go through all the varied movements of Betts' method with the military precision of a West Point drill, and with an apparent pleasure unknown to the military drill, and at the conversational recess have heard the hum of three hundred voices, at the tap of the bell, cease instantaneously, each half-spoken word cut short as by a flash of lightning. It is needless to say that the benefits of this method are not possible where the wasp-waists, the camel's hump and the kangaroo bend are cultivated; and it was pleasant to observe, in the school to which we have referred, that their distasteful and unsanitary demands were generally ignored by the pupils, their dress permitting the full benefit of the muscular movement. There was no occasion for the anatomist to ask, Where does Miss — keep her liver? how does she inflate her lungs, or keep her pelvic organs in place? what deformity does her bustle cover? Beauty and health are alike preserved by dress that preserves unconstrained the natural form of the body. Upon every attempt of the mantamaker to improve the masterpiece of the Supreme Architect must be written *failure*.

Every physiologist and sanitarian agrees with old Ben Johnson:

Robes loosely flowing, hair as free,
Such sweet neglect more taketh me
Than all the adulteries of art,
That strike mine eyes, but not my heart.

Utilitarians advocate manual training both as an exercise and as a co-education, arguing that, while it gives health to body and mind, and soul, too, for "the devil finds some work for idle hands to do," it should train the muscles to practical obedience to the will by giving instruction in some vocation that may be of special advantage to the individual and the world; that will enable the pupil to form an idea of what vocation he desires to follow; that will teach him to love useful employment rather than play; that will enlarge his soul and dignify honest labor.

It is asserted that three hours a day given to study, one to drawing and two to the shop educates the whole man, and that while the student makes as rapid progress in letters and science as when the whole time is devoted to them, he acquires a better knowledge of the mechanical art than those who serve a three years' apprenticeship, because the latter is for the benefit of the shop, while the former is for the benefit of the pupil, and that he obtains both a practical and a scientific knowledge of all representative implements.

While this course may not be generally applicable to the public schools, it emphasizes the importance of State, district and city schools of agriculture, mechanics and art. If there should be normal schools, at public expense, to teach teachers and agriculture, why not schools to teach artisans? The *Slojd* method now being introduced into American schools from Sweden, is well worthy consideration.

There are many children, as of miners, who are kept from school during the winter by necessary labor who should be provided for in a summer school, and in such a school manual training would be a beneficence. In all our larger cities such schools properly located would give the children of their dark alleys and slums, a healthful atmosphere, physical, mental, and moral, and prepare them for a useful and honorable citizenship.

Both boys and girls should have proper instruction in regard to sexual peculiarities, and upon the physical mental and moral diseases consequent upon abuse of sex. There are nameless physical vices acquired in childhood that tell upon the whole life. The school is the best place for their correction. Some may say to name them is suggestive. The argument applies equally to all sin.

In all school régime there must be a flexibility that recognizes sexual idiosyncrasy. Her rapid development into womanhood is a heavy tax on female life, and the educator must devise means to meet the contingency. Until she has safely passed her first climacterix all educational methods must regard this developmental period.

As an extensor muscle rests while its opposing flexor contracts, and as by this alternate action they permit much longer periods of labor than would otherwise be admissible, so if that portion of the brain through which memory acts is used alternately with those portions through which the reasoning and other faculties act there can be longer continued intellectual training without injury. Study should not only be alternated with amusement, muscular exercise and rest, but studies that call into action one faculty, should be alternated with those that exercise other faculties, thereby not only securing rest but systematic and healthful development.

RECESS AND VACATION.

In some schools fashion and the convenience of the teacher demand one long unremitting session. If it was not illogical the worn looks of the pupils, as it draws to a close, should sufficiently condemn it. Each half hour there should be a rest of five minutes. To some this may seem a needless interruption and waste of time, but it will secure greater improvement than when longer periods are given to pretended continuous study.

A large proportion of the children in the public schools are between six and twelve years of age, and in many places there are crowded into the lower rooms from fifty to an hundred children. The younger children are often sent to school for the convenience of the home, and their instruction should be conducted largely on Kindergarten methods, adapting the lessons to the restless life of the pupils, or they should be allowed a recess of each alternate fifteen or thirty minutes, gradually decreasing the length of the recess as the child increases in years.

The crowded condition that frequently obtains in our public schools should be obviated. Frequent recesses and ventilation may to a certain extent remedy the evil but cannot remove it. It is a wrong, moral, mental, and physical to both pupil and teacher. The only excuse for the overcrowding is the expense of more teachers and more buildings. As no vocation is more important than that which develops the life and moulds the character of the next succeeding age, no economy is more false than that which hinders the full round development of the body, mind and soul of those who are to constitute the coming age.

An important and unsettled question is whether the pupils, especially in the more advanced grades, should spend their recess in the school room or out of doors. If they go out it is too often to lounge idly around, frequently obstructing the sidewalk, about which hypersensitive people are sometimes hypercritical, or to engage in some such play as marbles, which gives neither exercise or spiritual elevation, or in over exercise that returns them heated and exhausted to the school room. The only advantage in going out of the school room is to get fresh air, which should come to them more easily than they can go to it. There is no need of leaving the room except for special purpose, which should always be permissible. We can hardly conceive of a teacher so senseless and inhuman as to refuse a pupil permission to respond to the calls of nature.

During the recess exercise, no matter how perfect the ventilation, the windows should be opened before it commences, and closed as soon as it is over. This exercise, in which the whole school should engage, conducted by a competent

teacher, will be as pleasant, and far more profitable than any taken on the play-grounds, no matter how well they may be adapted to the purpose, and the grounds about our public school buildings are rarely what they should be. The grounds about every school building, whether in the country or city, should cover a full square—about four acres, and should be artistically planted with trees, shrubs and flowers, giving sunshine and shade, and making the school form the one green spot in memory. At first blush this may be denounced as the thought of a crank, but it challenges examination. In the average ward school of our cities there are gathered from 500 to 1000 pupils. They need space for ventilation, and trees and shrubs for the healthful exchange of the exhaled carbonic acid gas and oxygen, and for the cultivation of taste, making the school grounds a place of beauty and a joy forever. They are thus made healthful not only for pupils and teachers, but for the whole city. Few cities have enough of these breathing places, and they are nowhere more appropriate than about their public schools. And who will object? The miser boards his pelf through love of self, but dies at last to leave it to his heirs. Dives may have no regard for the children of the Nation, but the philanthropist and patriot lives for his children and his country's children. Her public schools are the monuments of his love of country, and his interest in those who must soon sustain its honor and maintain its glory. All our accumulations are for those who succeed us. All the duties of life, all the affairs of state will soon be transferred to them. Shall we not make the places where they are prepared to discharge them healthful and attractive? Time was when any room, any where, was deemed good enough for a school, but the world moves. While our parents loved us as we love our children; while Washington said, in his Farewell address, "Promote, then, as an object of primary importance, institutions for the general diffusion of knowledge. In proportion as the structure of a government gives force to public opinion, it is essential that public opinion should be enlightened," they knew as little about the public school and of the relation of the public school to public health as of the telephone or the electric car. Our colleges and seminaries have long recognized the beneficence of beautiful parks. Why not provide them for the schools of the people? Let the State require them of the school district and of every city or village applying for corporate powers, and let the school boards see that their out buildings cease to disgrace humanity and to destroy health.

Those members of the committee who discuss the lighting, heating and ventilation of school buildings will probably decide them defective in the large proportion of both public and private

schools, and thus emphasize the importance of periods of rest, special ventilation, physical training and sanitary surroundings. It is frequently asserted that the child who wants to learn will improve under any teacher. It may be true, as an old Scotch professor once asserted, that "ye canna make a mon out o' mud," but we have equally good authority for asserting that the Master Mechanic did make him out of the dust of the earth. Teachers, like artists, are born, not made, and should mould the virgin clay placed in their hands into men and women worthy the name. This work lies largely in their ability to make knowledge attractive, and to induce pupils to seek it for its own sake rather than for the sake of some ulterior reward, or through fear of punishment. It is through such motives, their worry, anxiety and depression that education becomes a source of mental, moral and physical disease. Point out the possibilities of the soul, awaken the aspirations of the pupil, demonstrate the beauty of wisdom and the power of knowledge, teach how to use facts obtained for the attainment of other facts, put gladness into the heart of the child, make education joyous, lead forth the mind "in green pastures and beside still waters," and there will be healthy and harmonious growth. Tell a child how bad he is and he will be bad, how stupid, and he will remain stupid. The master who marches about the school room with a storm cloud on his brow, thunder in his voice and lightning in his hand, should be transferred to the kingdom of his satanic majesty, and the teacher who endeavors to instil knowledge through the back of the pupil should remember that "a rod is for the back of fools," of whom he is the chief. The only reason why corporeal punishment in government is restricted to children is their inability to successfully resist. It is cowardly and brutalizing and tends to make all educational methods hateful. "Love is the fulfilling of the law." The mid-day recess is of special importance, as it generally includes the principal meal of the day. Eating thus becomes an important part of the nooning. Children require food for both repair and growth. They should be taught to eat slowly and masticate thoroughly, and to eat with thanks and a glad heart, as sullenness and fault-finding during meals tend to indigestion and disease. They should have a nutritious and easily digested diet, and be encouraged to eat fat, as oil facilitates metamorphosis and is essential to healthy growth. The officers in the regular army are required to inspect every meal prepared for the soldiers and see that the rations are good, properly cooked and abundant, and that the men, selected for their robust health, are clean, well clad and housed, and have regular exercise. Are not its children as much the wards of a Nation as its soldiers? How much more important that

trustees, directors, teachers, parents, all who have charge of the children of the Nation should give careful attention to all that pertains to their health and development. Neither the mind nor body should be permitted active exercise immediately before or after a full meal. Digestion demands nervous energy, and if diverted by mental or physical action there will be indigestion, and mal nutrition. Children living long distances from the school should have a dining hall near by, or carry their dinners with them. Instead of eating alone, in a corner, there should be a proper room assigned for lunch, or a picnic in the grove that should surround the school building, where the children of the rich can exchange their luxuries for the homely fare of their poorer school-mates, learning that it is "more blessed to give than to receive," and finding good digestion in receiving and communicating joy.

During school life the importance of refreshing sleep, and enough of it, cannot be too strongly emphasized. Exciting entertainments, late study, everything that trenches upon the hours that should be devoted to sleep, or causes insomnia, must be avoided. The "six hours sleep for students and eight for babes and fools," is as senseless as "Graham gems for students." The development of a strong mind in a strong body requires a nourishing diet, plenty of exercise and plenty of sleep, and a time for everything and everything in its time.

Action in any part of the body destroys tissue, but it carries an increased flow of blood to the part, increased cell proliferation and vital force, and increases the demand for rest and repair.

Vacations should embrace the warm months—July, August and September—and the long session should be broken by a fortnight's rest at Christmas, and perhaps a week at Easter. During the long summer vacation the pupil should seek physical development by engaging in home labor, or by a summer outing, according to pecuniary ability and residence.

Some sanitarians advocate one long school session. Permit me to quote from a paper read before the Kansas State Sanitary Convention, 1886, which I still endorse:

"The protracted daily sessions practiced in some places are unsanitary. They may minister to the convenience of the parents and teachers, but they violate every principle of school hygiene. In childhood and youth the brain and muscle, because of their ready wear and tear, soon tire, but they are quickly renewed if opportunity is given for repair. The long five hour sessions not only cause excessive exhaustion from long continued labor, but they give no time for dinner, a necessity to the growing child, who should have three meals each day, with an ample meal at noon, with time to eat and digest it. . . .

A sufficient nooning, with a meal near at hand, is a school necessity.

"When the five hour system is practiced, a single glance, during its last hours, at the worn, weary and anxious faces of the pupils, and at the unseemly haste with which they leave their *prison-house*, are sufficient to condemn it. Long continued attendance, with fixedness of muscle or mind, are incompatible with health at any school age."¹

STUDY—TIME AND AMOUNT.

Very few persons are ever injured by study properly pursued. Regular, methodical brain work, adapted to the physical and mental strength of the student, is as healthful as other labor. It vitalizes while it stores the mind with useful knowledge and keeps alive interest in the world of thought and duty. Dunglison in his *Human Health* says, "Literary pursuits are directly favorable to long life, whether they require the exercise of the memory, the judgment or the imagination, and when the health is apparently injured by them the evil is dependent rather on collateral circumstances." Mental development is in harmony with all we know of the laws of life. It is only its methods and associated conditions that injure. All education must keep in view the importance of such development of the spiritual powers with which the Creator has endowed man as will secure the greatest good to the individual and to the world. Pure intellectual culture does not control a tendency to debauchery and crime. Education must develop those powers that hold in subjection the appetites, passions and desires, that, unrestrained, unbalance the mental and moral forces and tend to disease and death, transmitting hereditary tendencies that produce physical, mental and moral debasement in the whole line of posterity. *Morality*, the righteousness of right thinking and right doing, must form a part of all education. "Virtue and morality are a necessary spring of popular government." Their culture involves a knowledge of the meaning of our existence, and the existence of the world about us, a knowledge of the final causes of the universe. Though theology, as commonly understood, should not enter into the education of our public schools, a knowledge of God and humanity, and of our relations to both, is essential to the public good. Nothing else will press home to heart and mind the duties we owe to ourselves and to each other as component parts of a great government, as members of a common family. Nothing else will keep alive interest in those governmental measures and methods that protect the health, and secure the development and prolong the lives of the people.

The physical as well as the mental and moral health of the pupil is injured by the sensational novel that unduly excites passions and emotions that should lie dormant in childhood. Every book with an impure, hidden meaning should be as far removed from children as those that indulge in open infamy, and both the minds and morals of children are debased by the detailed and realistic reports of crime that occupy no inconsiderable portion of the daily press.

"Vice is a monster of so frightful mien
As, to be hated, needs but to be seen;
Yet seen too oft, familiar with her face,
We first endure, then pity, then embrace."

If the public stomach did not demand it the newspapers would not wallow in the gutter of moral filth to gratify its appetite. Where can the public taste be corrected and the moral purity and strength of the nation be developed better than in the public school?

The machine work so common in many schools is responsible for much of the disease charged to education. All school methods must possess a certain amount of flexibility. Every child has its idiosyncrasy which the successful teacher must give, as do successful physicians, the fullest possible consideration, and during school life there are additional exigencies, such as the passage from girlhood to womanhood, that cannot be safely ignored, and that demand relief from worry, rest from work and protection against inclement weather, without a demand from the *master* of the why and the wherefore. He should know enough of physiology and psychology to understand that girlhood has functions that a proper delicacy does not care to reveal.

Though we may not measure the effect of certain conditions, or the force brain or muscle may safely exert under special stimulants, or how long they may be continued, we know there are limitations that vary in different individuals and under differing conditions, and that the power of continued endurance is never so great in childhood as in mature life.

Long continued, unintermitting action, whether of brain, muscle or gland, exhausts nervous excitability. The nearest approach to perpetual activity is found in the involuntary muscles, but there nature provides alternating action and rest, systole and diastole, inspiration and expiration. Rest is as necessary to recuperation of brain as of muscle. Sir Walter Scott, when asked how many hours he devoted to study, replied, "I reckon five and a half hours a very good day's work for the mind when engaged in original composition. I can very seldom work six hours, and I suspect what is written after five or six hours of hard mental effort is not worth much. I try to get two or three of these hours in before breakfast, and the remainder as soon after as may be,

¹ "The Sanitary Conditions of School Houses and School Life," by W. L. Schenck, M. D., Annual Report of Kansas State Board of Health, 1886, p. 184.

so as to have the afternoon free to walk, or ride, or idle."

If the strong mind of England's great author could not endure more than five or six hours of daily mental effort, what are we to think of the educator who would work his immature pupils all day and half the night?

After the long fast of the night, most persons require a light breakfast, preceded by such exercise as comes from a morning bath, followed by a good rubbing, before commencing study. For the school child the bath, home chores and the school road are exercise enough for the morning, and three hours of study during the morning, less the amount deducted for conversation and calisthenics, and three hours after the nooning, is study enough for children commencing their 'teens, with an hour or two in the evening as they grow older.

INSTRUCTION IN HYGIENE.

If practical hygiene is important to school life, pupils should be taught, as far as they are capable of comprehending, the principles upon which it is based, and its application to the broader fields of life upon which they must soon enter. If the development of the intellectual, moral and physical forces of the children of the nation is important, their preservation is not less important. This involves a knowledge of the laws of life and the causes of disease, and the means of their prevention, removal or restriction. Biology and physiology, etiology and preventive medicine, should form an important part of all education. Properly pursued, they interest while they instruct, and while they store the mind with knowledge of vital import, they stimulate to investigation and research. And when the electors of a State and their representatives have learned that through vaccination properly enforced by all nations, small-pox will exist only in history; when they understand that filth accumulations not only infect the air we breathe, the water we drink and the food we eat; not only engender and intensify septic diseases, but make every injury and disease more formidable, there will be adequate legal provision for the protection of the health and life of the people. How is this to be known unless taught? how taught without a teacher? Many of the States provide that physiology and hygiene, and the relation of alcoholics to health, shall form a part of our common school education. But as comparatively few of the teachers in the public schools have more than a crude and elementary knowledge of these important branches until they acquire the required knowledge, the State should provide special instructors to teach both teachers and pupils, and the instruction should be as far as possible macroscopic, microscopic and chemical, by lectures and through scientific text-books.

PREVENTION OF CONTAGIOUS DISEASES.

It is the duty of the State to protect those it gathers into its public schools, and to protect the community against the diseases that may be disseminated through the school, while private schools that fail to extend known and needed protection should be held for the disease they occasion. Childhood is especially susceptible to infectious and contagious diseases, both because of its impressibility and its lack of exemption through contact, and in childhood many of the zymotic diseases are especially grave. In America the free schools gather their pupils from all classes and localities, and for many hours keep them in crowded rooms and in the closest personal relations. In no other assemblage of human beings is there greater opportunity of contracting and spreading contagious and infectious diseases.

When a contagion appears in a school, there is sometimes a doubt as to the best course to be pursued. The common one is to dismiss the school. When small-pox comes to a private house, we isolate the individual case, disinfect and vaccinate all who have been exposed, and keep them under strict surveillance until danger has passed. When yellow fever invades a city, we throw a cordon about it, and prevent those who can carry with them the contagion from leaving the district until safety is assured. When a case of small-pox occurs in a college it is isolated, those who are known to have been in contact with it are kept under inspection, while all others go to their several homes. Why? If they have not been exposed to the disease, while those who have are isolated, why not continue the college exercises? If they have been exposed, sending them away may communicate the disease to those they meet *en route*, or establish it at their homes. Scarlet fever, diphtheria or measles occurs in a public school. What shall be done? Dismiss the school? Yes, if it is best to turn those that have been exposed into the street, that they may carry the disease whithersoever they will. Is it not better to have existing cases isolated, those who are known to have been exposed reported to the health officer, the rooms where they attended thoroughly disinfected, and the school continued. Is not this better than to give those *who may have been* exposed the freedom of the city? When a grave epidemic prevails, the conditions are changed, and the public school should be closed.

It is hardly necessary to say that children from a home where a grave contagious disease exists should not only be kept from school, but from the street, and should be thoroughly disinfected before they are permitted to return to society. What are the grave diseases that should exclude from school and from society? On this question

sanitarians may differ. Some may include consumption, others typhoid fever. All are not agreed that the former is contagious, and its course sometimes covers enough of life to exclude a whole family from all school privileges; the latter, communicated through discharges from the alimentary canal conveyed to the alimentary canal, will hardly be carried to school. Small-pox is still the terror of the people. For ages it was the great destroyer, attacking one-sixth of the entire population of the globe, destroying one-half of those attacked, robbing those it spared of their comeliness, and often of all hope of health. While to the unprotected it is as virulent as ever, since the discovery of the immortal Jenner it is easily shorn of its power, the possibilities of contagion being reduced to a minimum by a measure that rarely involves either hardship or danger. Neither the incipient insanity of the crank, nor the unrighteous greed of the quack, who would fatten on its desolations, should be permitted to allow any child to enter a public school until properly vaccinated. When a case occurs in a school district, there should be revaccination until no effect is produced. To make assurance assured, children from the home where it exists should not be admitted to the school, and should be kept from the street.

Diphtheria, scarlet fever, cholera, yellow fever, measles, mumps, pertussis and scabies, should exclude children from the homes where they exist until safety is assured through the certificate of a proper health officer.

As that which is to be is evolved through that which now is, the State has no more sacred duty and can have no grander aspiration than the protection of its children from all that deteriorates, and the development of all that strengthens and ennobles.

A CONTRIBUTION FOR DEFINITE AND KNOWN QUANTITY AND QUALITY IN MINERAL WATERS.

Read by title at the Meeting of the Mississippi Valley Medical Association, Oct. 14, 15 and 16, 1891, held at St. Louis, Mo.

BY GEO. F. HULBERT M.D.,
OF ST. LOUIS, MO.

As medical science steps forward in her ceaseless stride for more and better understanding of disease in the human economy, so too is the desire and necessity created for better and more efficient means of relief. The study and use of the armamentarium at our command for this purpose has gradually and steadily brought before us that exceedingly valuable class of remedies known as mineral waters.

Nature, in her beneficial and bounteous provision for the wants of mankind, has herein provided a weapon of defense, which, unfortu-

nately, has not commanded the special attention of the profession *en masse*, but has been accepted and utilized by only the few. Why this has been so is easily understood.

1. The presentation of the character and value of mineral waters has only too frequently been in the lines of the charlatan and unscientific, advertised by those interested in a reckless, catch-penny style, and certified to by those who are incompetent to diagnose the conditions for which they are desirable or applicable.

2. The necessity of proceeding to the source of supply for the full benefits on the part of the patient, or accepting the admitted makeshift, purchase and use of the waters at home, put up and prepared only too frequently in an altered and inefficient condition.

3. The failure on the part of the profession in the use of natural mineral waters as presented in the open market to get results claimed by those interested.

4. Those who have overcome the difficulties presented have, speaking in a general way, done so by the use of the artificial product.

The subject is of sufficient importance, and the benefits to be derived are of such a character, that we feel compelled to speak plainly, and to the point, as to the why and wherefore of this discrepancy, in order that the way may be pointed out to intelligently evade the difficulties and disappointments.

It is agreed that the therapeutical value of a mineral water is dependent upon the quality and quantity of its solid ingredients, and the temperature at which it issues from the earth. Dr. F. A. Struve, of Dresden, more than eighty years ago clearly established the fact that the composition of a mineral water was due to the dissolving of mineral substances from the geological strata through which the water passed, through and by the aid of the solvent gases (carbon dioxide), a more or less high temperature, and the action of increased pressure in the interior of the earth. The water then, at the *mouth of the spring only*, will contain its full development chemically and exert its full effect medicinally.

The mineral substances composing the active principles of mineral waters are mainly soluble alkaline and earthy salts, and such metallic ones as are readily soluble, but whose solubility is quickly changed by various combinations with oxygen. The omnipresent oxygen of the atmosphere, the volatile propensity of the carbon dioxide, the release from pressure, as well as change in temperature, necessitates an almost inevitable prompt chemical change on the escape of the water from the spring. This is specially noticeable in the ferrous and manganous waters. They are seen bubbling up in clear, sparkling, pure compositions from the bottom of the spring, which, upon discharging into the open air,

promptly and fully precipitates the sensitive metallic salts in the form of the insoluble ferric and manganic salts. In those waters containing the earthy carbonates, the release from pressure on their appearance at the surface of the spring at once precipitates them as mono-carbonates by setting free the other equivalent of carbon dioxide. This would not have occurred if the proper degree of pressure had been maintained.

At Carlsbad, the hot "Sprudelwasser" forms a thin, earthy and ferric carbonate on the side of the glass while the patient is slowly emptying it, thus proving the prompt and almost immediate decomposition of thermal waters.

Dr. Geo. E. Walton, in his "Mineral Springs of the United States and Canada," page 113, says: "There is not the care used in bottling waters that should be observed, and there are but few waters that are adapted for shipment."

From the above, it is readily seen that only at the spring itself are we positive and sure to receive the water as Nature has elaborated it and prepared it for the use for which it is applicable.

It is well to remark that the mysterious occult properties so much enlarged upon by the parties interested in any particular spring or springs is not comprehensible to the scientific mind, but must be referred to the personal equation of the patient. The real fact that is thus presented consists only in the *combination on the part of Nature of conditions accomplishing a certain purpose* that gives a value to this or that spring. To the uninformed this is unknown, therefore occult; to the chemist it is determinable and known, therefore ceases to be occult.

As regards the question of analysis of the waters as actually presented by Nature, there have been and are to this day many chances for error and careless work, but the scientific chemist of to day is perfectly competent to determine the exact ingredients and their quantity, so that the statement made by some of the impossibility of giving a correct analysis will not hold good.

The essentials for this work are as follows:

The analysis of a mineral water must commence at the springs. Its temperature must be ascertained at different times of the day, and its relation established to the temperature of the surface.

The emission of gases, and their nature, has to be observed, and samples of the water mixed here, with known quantities of re-agents, to determine the quantities of free gases contained in the spring. The water to be examined at the laboratory should be carefully filled into glass-stoppered bottles from underneath the surface of the spring, in order to avoid any and every decomposition by access of the air. Chlorine, sulphuric acid and silicic acid must be determined in separate quantities of water; iron, lime and magnesia are determined in the same quantity of

water, one after another, as it is necessary to separate the iron before you can determine the lime, and this substance before you can get at the magnesia.

The alkalies must be determined in a portion of the water from which iron, lime and magnesia have become separated by such processes as do not add any alkaline substance to the water. Aluminum, barium, strontium and manganum oxide or protoxide, as well as phosphoric acid and iodine, bromide and other substances which usually occur in mineral waters in but small quantities, are determined from large quantities of water concentrated by evaporation in such manner as to obtain also the volatile substances in separate vessels and solutions.

If carried on correctly, and the water for analysis has been obtained at and from the springs in the proper manner, all volatile and solid ingredients can be determined by the expert chemist, except the mysterious soul of the spring which is attributed to them by people who believe in supernatural powers in mineral-water springs.

In the very nature of things, then, the great labor, expense and scientific knowledge required to properly comprehend and overcome the almost insurmountable difficulties, do we see why it is that mineral water, as found at the springs and in the market, differ so much in quality and results attained by their use. The door is open to all sorts of deception, and the results of accurate scientific investigation of many of the products presented in the open market and sold as the real genuine natural product, are startling in the discrepancies discovered.

As illustrating the facts discovered, the "Carlsbad Sprudel Salt" was found to contain 85 to 98 per cent. of glauber salts, when the analysis of the water at the springs showed the percentage in the solid contents to be only about 45 per cent. Again, in the Apollinaris, it is found to have no iron and much salt, due to the manner in which the water is obtained and put up, while at the springs iron is present and much less salt.

Again, in "Determination of Lithia in Mineral Waters," by E. Waller, Ph.D., a paper published in the *Journal of the American Chemical Society*, Vol. XII, No. 6, we find further testimony of unreliability in "quality and quantity" of the several natural lithia waters as presented for sale in the market. After giving the three methods non-available for determining the amounts of lithia salts—1, the phosphate method (Mayn's modification); 2, the amyl alcohol method (Gooch); 3, the flouride method (Carnot)—in all of which the spectroscope test is applied for control of errors, he arrives at the following definite results:

In the Farmville Lithia Water, after repeated experiments with large quantities of the water

(10 litres), concentrated by evaporation only, sufficient lithia was found to produce the lithia line in the spectroscope, but not enough for quantitative estimation. With the Buffalo Lithia Water the reaction for lithium was more distinct when considerable quantities of the water were concentrated. From 20 litres of the water was obtained lithium sulphate corresponding to 0.0185 part Li. H. CO₃ per 100,000 of water.

Dr. Karl Luedeking, chemist at Washington University, in making an analysis of the No. 2 Spring water of this concern, failed to find any lithia whatever.

The Londonderry water gave the lithia reaction without much difficulty, being a little over 4 parts to 100,000. "The company puts up some of the water in half-gallon bottles (called in their circulars 'Sulpho-Carbonated'), which is charged with CO₂, and has also received the addition of some salts. The amounts of salts added appear to be somewhat irregular. For instance, the following results were obtained in parts per 100,000 of the water :

Half-gallon bottles,	37.35	total solids.
Pint bottles A.,	149.4	" "
" " B.,	104.2	" "
Average of 11 others,	224.7	" "

The proportion of lithium was the same as for the still water."

This extract, taken from the paper of Prof. Waller, in connection with the further statement that at several times the water has been found to contain no lithia whatever by other competent chemists as well as by himself, as well as the fact that none of the water can be obtained from the springs by disinterested parties or visitors, all access to the springs being denied, and applications for water referred to the bottling establishment in Nashua, needs no comment from us; the facts speak for themselves.

The Saratoga Hathorn proved to be the strongest lithia water examined, and contained the full percentage the analysis calls for (12 to 14 parts Li. H. CO₃ per 100,000 parts of the water, corresponding to $\frac{7}{8}$ grains per U. S. gallon).

One of the most difficult class of waters to handle away from the springs is the Ferro Manganous. We are pleased to give honor and credit to one of these springs, at least, for a determined endeavor to meet the requirements, and that is to the *Excelsior Spring Co. of Missouri*. They have simply accomplished all that can be done in the direction of presenting their product at a distance from the springs in its natural composition. The water of the spring referred to, "The Regent," is a Ferro Manganous water. It is only put up in bottles. The supply pipe to the bottling rack is started well down beneath the surface of the spring, a large hood being on the end; the water is then carried direct to the bottling department through pipe and pump.

Carbon dioxide is forced into the empty bottle, thereby expelling the atmospheric air from it; then it is filled with the water under high pressure of carbon dioxide, and securely corked. In this way at no time does the water come into contact with the oxygen of the air, and therefore retains its delicate chemical composition. It is consequently rare to find any precipitate in the "Regent Water," as it is called, of this spring, clearly proving the fact that its composition is the natural one. For a water of its class it is not excelled by any, and to those who can go to the springs, the "Regent Water" and the "Elms" are a delightful, health-giving combination to enjoy.

With the known variation from time to time in the proportion of ingredients of mineral waters at the springs, as well as the exceedingly weak impregnation of most of them by mineral substances necessitating the use of large quantities for very long periods, and the undoubted liability to and fact of their alteration, adulteration, chemical variability as compared to the natural product at the springs, it is not at all strange that the profession at large has little satisfaction or confidence in their use. In all cases where we get definite results, it is due to the fact, that we have a water of sufficient power and quality. The attainment of results being the exception, what can we do? *Use what we know has a definite quality and quantity at all times and results will be definite.* Hence we find a legitimate and useful field for the artificial product. *The necessary source for the artificial product is an honest, competent, scientific chemist.*

The following is taken from Liebig's Chemical Dictionary, 1851, Vol. v, p. 320. "Prompted partly by scientific interest and partly by the desire to offer to sufferers who live long distances from mineral springs an opportunity of enjoying their beneficial action, efforts were made to reproduce these waters by artificial process—and in the course of time this end has been attained with such perfection as to permit the artificial product to place itself along side of and compete in every respect with the natural mineral waters." This is authoritative commendation of honest and scientific labor, the pioneer in which was Dr. F. A. Struve, of Dresden, who established and proved not only by actual experiment the theory of the natural formation of mineral waters, but produced the first artificial Carlsbad water and administered it in conjunction with Dr. Soltmann, in the first season to over 300 patients, with results fully as satisfactory as attained in the use of the natural Carlsbad Sprudel at the Springs. The good work has progressed until to-day, when there is no mineral water of any positive value which has not been satisfactorily manufactured, and best of all, there is no mineral water known that cannot be and is successfully

modified or improved to meet the determined requirements of any disease for which it may be of value. In this country humanity as well as the medical profession is under lasting obligations to two gentlemen who have, in spite of every conceivable obstacle that could be thrown in their way by interested parties of mineral springs and products, steadily and persistently applied their scientific (medical and chemical) attainments and means, to the end that there should be presented to those desiring them, artificial or manufactured mineral waters of a positively known and definite value as relates to quality and quantity of solid ingredients, and thus insure efficiency and prompt results in their use. We refer to Carl H. Schultz, of New York, and Dr. Enno Sander of St. Louis.

It is only those who are familiar with the mineral water question and the celebrated mineral water controversy, "that can appreciate" the work accomplished by these gentlemen, and when we consider that scientific precision in the manufacture, honesty of purpose in the presentation of their products, and broad scientific equipment and attainments in qualification for the work they had in hand, have been the motive and power behind the throne, "damning with faint praise" is simply an impossibility from any one actuated by the principles of truth and honor.

Our practical experience with the manufactured product has been confined to that of Dr. Enno Sander, of St. Louis, and for the purpose of demonstrating their purity and efficiency we desire to call special attention to only three of the waters of this laboratory. "The Tenfold Carlsbad Sprudel," the "Garrod Spa" or "Lithia Potash Water," and the sparkling "Benzoated Lithium Water."

The Carlsbad Water is made in three strengths, the single, double and tenfold; the purpose of this being to enable the consumer to get the full advantage of the original *thermal* effects, without exposing the manufactured water to the risky and decomposing influences of heating each dose. This is at once accomplished by taking an equal or many fold quantity of hot water, adding direct from the bottle the necessary quantity of the mineral water and at once drinking the same.

The value of the Carlsbad water is beyond controversy and cavil in most hepatic troubles and many gastric intestinal diseases; hyperæmic conditions of the liver from whatever cause are most frequently relieved. This one therapeutic effect is of extended range. Frerichs testifies in no doubtful manner as to hepatic diseases. Niemeyer is exceedingly explicit as to the value and benefits derived in gastric catarrh.

As illustrating the efficiency of the Sander's artificial product, we present the following case of hepatic hyperæmia and catarrh of hepatic

ducts and duodemia, with the development of biliary gall stones, treated by the use of the "Tenfold Carlsbad Water." J. H. P.: American aged 50; came under my observation January 1st, 1889. His family history was a remarkable one of intemperance and abuse of alcohol. His father, three uncles, both grandparents (male) and three brothers were what to-day in common slang would be termed "steady lushers," with no choice as to quality of liquor consumed. No history of rheumatism, gout or nervous disease, but in all there were intestinal and gastric troubles. Individually the patient had been a constant steady miscellaneous drinker from 28 years of age up to 46, rarely what he considered intoxicated. All during his life and up to this time had never been sick or incapacitated from his labor, that of bank teller. Since 46 years of age he has been temperate, rarely using anything. About two years ago, without any apparent cause or deterioration of his general health, he began to suffer with pains in the right lumbar region, more like a soreness or oversensitiveness, not aggravated by motion. The attack would commence every night from 9 to 11 P.M., and become sufficient in severity to disturb his rest; relief was usually attained in an hour or two by means of hot mustard applications. This deviation from health was accompanied by rectal disturbances in the way of a prolapse of moderate severity, and continued for a period of six months with no apparent aggravation, when pain was noticed in left part of right hypochondria. This, while, like the other pains, was more severe and developed an ill-defined sense of threatened danger. Shortly after, bleeding of the abdomen supervened and his nightly sense of misery became more severe, to the degree that medical advice was demanded. "*Parri passu*" with medical attendance his sufferings increased, demanding opium for relief, until the crisis was at last reached by a severe attack of nausea and vomiting and the appearance of a pronounced attack of jaundice; pains ceased, jaundice gradually disappeared and for nine months he was a well man in his own opinion. The second attack then supervened, passed through the same stages, save that it lasted only ten days and was tenfold more severe. Clay colored stools were noticed during this attack; the lumbar distress did not entirely subside with the close of this attack, but nightly visited him for about two months, when his third attack came on, less severe than the second, but requiring three grains of opium every night to relieve it; it prolonged, up to the time we first saw him. Examination revealed a moral coward in a man of education and intelligence, completely cowed by his sufferings; fat and flabby of tissue, skin dry, tongue heavily coated, bowels fairly regular, appetite fair, urine smoky with bile reaction;

sensitiveness over duodenum and ileo cæcal valve, no distension of the bladder detected, liver enlarged, but not sensitive. Every means and method of treatment found on the books or known to us was faithfully tried. That seemingly giving the most temporary relief and keeping things in abeyance, was the use of *dioscorea villosa* in conjunction with *papaya carica* and saline purgation. The sweet oil method was a total failure. By the above means it was possible to dispense with opium save now and then. Close and continued examination finally revealed biliary hepatic stones. No large concretions were found at any time. This cleared up the question as to the part played by the condition of the hepatic ducts, and Carlsbad Sprudel water (Sander's) was selected as the sole therapeutic measure. A wine glass of the tenfold strength in a goblet of *hot water* was used three times a day; in one week his pains entirely ceased, general health began to improve and in one month he was symptomatically in his normal condition. The water was continued for three months steadily, when it was cut down to a single dose at bed time and kept up for two months more. He has not had an attack since; from time to time he uses the water as a safeguard on his own responsibility.

Another case of hepatic disturbance in which the condition seemed from the evidence to be inspissation of the gall, coming on at irregular periods, occurred in J. A. R., a Pullman palace car conductor. His attacks were preceded by a period of constipation and gastric duodenal distress lasting for about a week, when a severe attack of hepatic colic would develop, gradually and steadily increasing, reaching its acme in severe nausea and vomiting. No jaundice was present nor has been at any time. Free saline purgative usually brought temporary relief. He was placed upon Carlsbad water tenfold (Sander's) and for nearly two years has not had an attack; the water was used steadily for six months.

The formula of the Sander's Carlsbad is that of the Natural Carlsbad Sprudel, as determined by the analysis of Berzelius and Bauer; being rich in its proportion of sodium sulphate, carbonate and chloride, and positively uniform in strength, it is readily seen, why in its use we are enabled to attain uniform results. In the use of the Carlsbad water it is necessary that the same care and conditions be attained in its administration as at the springs. It is an alkaline *thermal* water, it must therefore be used hot, 112° to as hot as can be borne. The range in temperature at the springs is from 112° to 152°. The best time for use is an hour before or two to three hours after eating. Used with these precautions and for a sufficient length of time, no one will fail to get definite and positive results from its use.

In our consideration of the Garrod Spa, the Lithia Potash Water, and the Benzoated Lithium Water of Sander's Laboratory, we are in a position to speak positively as to their value in rheumatism, gout, lithiasis, and allied disorders, having absolutely discarded from our armamentarium in the handling of these diseases, all other internal medication save that needed to meet complications for the time being. It is entirely unnecessary to enter into an extended consideration of etiology, symptomatology, or unsatisfactory therapeutic experiences of the part in the management of these diseases; sufficient to say that to-day the Garrod philosophy, interpretation, comprehension and treatment of gout, rheumatism and allied disorders is the only conception that can be successfully sustained. In brief, that it is some interference or defect in the metabolic changes which take place in the human economy resulting to the presence of an excess of uric acid, that the alkaline method of treatment is the most effective yet presented.

In a paper recently read by Sir Wm. Roberts before the Royal Medical and Chirurgical Society, we find much light thrown upon the immediate determining cause of this excess of uric acid, and observations of exceeding importance regarding the behavior of the same in the blood and tissues and especially interesting in regard to the phenomena of gout. He demonstrates the fact that uric acid in the blood exists in the form of the *soluble quad-urate*. Under certain conditions, where the alkalinity of the blood be lessened or the excretion of the quad-urate by the kidneys be delayed, the acid combines with the sodium carbonate and forms the bi-urate of sodium, a salt exceedingly insoluble in blood serum. Synovia being less alkaline than the blood, it is suggested, that this may account for the deposit of bi urate crystals in and about the joints. The immediate effect being to relieve the blood of the excess of acid; this at once becomes consistent with the chemical phenomena observed after an attack of gout. The periodicity of gout is explained by what he terms the process of "maturation," which is the progressive taking up of the quad-urates by the blood and fluids of the body, when finally the point is reached (possibly saturation), when it suddenly breaks up into the bi-urates and precipitates, earlier in the synovial than in the blood tissues. The stage of solution was hastened by increased alkalinity of media; no appreciable effect in retarding the period of maturation and precipitation was produced by this means, and the addition of salts of sodium notably hastened the process. The addition of salts of potassium, lithium or magnesium did not appear to have any effect either way, save the chloride of potassium seemed to prolong the period of maturation. The *factor* in determining the duration of the period of maturation was the

proportion of uric acid, hence the necessity for caution in administering alkalis, which if administered when the blood is near the point of saturation by uric acid, or near the close of the period of maturation, may, by favoring the formation of the urate, precipitate an attack of gout. Taken earlier when the margin of solubility for the uric acid is greater, the alkalis will facilitate the conversion of the acid into the quadrates and present them for elimination by the kidneys. This accomplished freely, the danger of an attack ceases. It is clear that large quantities of water are needed. From the above it is evident, and the observations tally with experiences in the management of these troubles, that to receive the full benefit of the alkaline treatment, elimination by the kidneys especially is paramount; this absent, then the skin and bowels must be brought into play. The sodium salts are not desirable, and moreover the treatment must be sufficiently prolonged to overcome not only the direct exciting cause, but also possibly delayed, by treatment, the period of saturation.

The above researches also give us valuable suggestions for therapeutics and combinations to meet especial conditions. In the administration of alkalis it would seem proper that we have two formulas, the one for the milder manifestation such as the rheumatic, where apparently, according to Dr. Roberts, the process may be considered the accumulation of the excess of uric acid and delay in its passage into the quad-urate, giving us the inflammatory stage by toxæmia, so to speak, and the other where the process is more fully developed passing into the stage of quad-urate formation with the ultimate precipitation of the bi-urate in crystals and concretions, giving us inflammatory phenomena more directly if not wholly by mechanical effects.

It is beyond controversy that the lithium carbonates or preferably bicarbonates, are of pre-eminent value. In the light of Dr. Roberts' observations it may be suggested that the most easily broken up bi-carbonate of lithium, might be, being present in the blood, that as the quad-urates were produced, they would select the former in preference to the carbonate of sodium, thereby producing the soluble urate of lithium, and not the insoluble bi-urate of sodium. In order that the degree of alkalinity be not too pronounced or perniciously hastened, the guarding of the process by the benzoate of lithium, would not only offer more lithium for conversion into the soluble urate of lithium, but by setting the benzoic acid free, would insure the acidity of the excretion, the urine, as well as prevent too much alkalinity of the blood. Hence we find the Lithia-Potash water best adapted for the rheumatic, and the Benzoated Lithium water for gout, rheumatic gout, renal and vesical concretions. It has been our practice to use the latter in all

acute severe rheumatic conditions, until they were controlled, then change for the steady, long continued use to the former, the "Garrod Spa" water. In gout, rheumatic gout, gravel and vesical concretions the benzoated has been of most value until the morbid process was well nigh completely overcome. The formula is follows:

R. Lithium Benzoate, gr., 12.823.
Lithium Bicarbonate, gr., 13.784.
Potassium Bicarbonate, gr., 10.000.
Sodium Chloride, gr., 10.000.
Carbonated Water, 5xvj. ʒj.

The usual dose is one third pint three times a day between meals and at bed time; in severe cases increased to one half pint at same time of day until symptoms are under control; then the former dose.

The "Garrod Spa," named after Dr. Garrod, is the above formula with the lithium benzoate omitted. These formulas are not susceptible of being compounded by simple mixture, but must be produced under pressure and in the nascent state, hence require skill and caution in manufacture.

As in demonstration of their great value and reliability we desire to present the following brief case records for consideration.

Mrs. M.: Mulatto aged 30, was taken with a severe attack of neuralgic rheumatism. Her environment was miserable in every respect. The symptoms were for a time quite puzzling, resembling in many points a case of trichina. At no time was there any synovial inflammation and only at a late stage were the fibrous structure about the joints involved; we were not able to find a voluntary muscle which was not exceedingly sore and tender to touch. Movement was impossible without agonizing pain. Emaciation was rapid and temperature ranged from 101-103°. For three long months did we medicate this patient with alkalis and all other drugs considered of any value, until she and her physician became thoroughly disgusted. Having only attained slight amelioration of her sufferings, finally selected the Garrod Spa (Sander's) on the recommendation of a brother practitioner. In two weeks the symptoms began to abate, in six weeks she was able to walk and in ten weeks she was symptomatically well. This was our first experience with artificial mineral waters, and we were inclined to be a convert. The next case presented occurred in the St. Louis City Hospital under the care of Dr. H. C. Dalton, a woman pregnant, suffering from rheumatism. The following report from Dr. Dalton will suffice.

OFFICE OF CITY HOSPITAL,

H. C. DALTON, M.D., Supt. and Surgeon in Charge.
ST. LOUIS, MO., Oct. 10, 1891.

DR. GEORGE HULBERT, 3026 Pine street:

Dear Doctor.—Your card of yesterday received. Christy S. was admitted to this institution May 22, 1891, suffering from a very acute attack of articular rheumatism. She was in her fifth month of pregnancy.

The rheumatism developed three days prior to her admission to the hospital. I saw her shortly after admission, and found the following condition: Left knee greatly swollen; complained of great pains in right hand and arm, both of which were swollen. A few days after admission, her left wrist and right ankle became greatly swollen and acutely painful.

She was given large doses of salicylate of soda, which gave her but little, if any, relief. The changes were rung upon the various remedies for acute rheumatism without avail. After July 6 she was given a bottle daily of Benzoated Lithium Water (Sander's). In a few days marked improvement was observed. On August 12, patient was free from pain and able to sit up, the swelling having entirely disappeared from her joints. In fact, she expressed herself as feeling entirely well, though still quite weak.

She has not had the slightest symptom of the disease since. On the 3d ult. she was confined, and has done well since. After taking the Benzoated Lithium Water for ten days, the amount administered was increased to a bottle and a half daily.

Very truly yours,

H. C. DALTON.

The next case was that of J. R., aged 35, a telegraph lineman of splendid physique and strength, accustomed to all sorts of hard labor and exposure; is temperate in all things. Had noticed for several months at times that his urine was very high colored, with the brick-dust sediment. He first came to me in January, 1891, complaining of rather severe pains in right lumbar region, which came on suddenly and lasted for about two hours. His urine the day or two before was quite well charged with the brick-dust sediment. The first time of emptying his bladder after the above attack of pain he noticed that it was bloody, and on standing in bottle for a short while, the quantity of blood and mucus would extend half way up the depth of fluid. In a few days this attack passed away under the use of simple medications. Occurring at intervals of two to four weeks, the patient had four more experiences of the above character, except each one was of a decidedly more severe and grave degree, until the last one lasted two weeks, and confined him to his bed. The urine in this attack was to all appearances mostly blood, and, on standing, the entire depth of fluid in bottle was filled with sediment.

From the suddenness of onset of symptoms, the hematuriae, the pain, and presence of gravel in the urine, renal calculi were suspected, and it was decided, after making a fair trial of medication and no results were attained, to operate and remove the stone from the kidney. The Benzoated Lithium Water (Sander's) was selected for the trial. Since using this water, one-third pint three times a day, he has not had another attack, nor has there been the slightest indication of gravel in the urine save in September, 1891. Thinking he was all right, he stopped, in August, 1891, the use of the water, and one day in the latter part of September, 1891, had a touch of his old lumbar pain, and noticed his urine was smoky. At once he began again the

use of the Benzoated Lithium Water (Sander's), and is still using it. The presumption is that there is a stone in the pelvis of the kidney which is being slowly dissolved, for otherwise we are at a loss to account for the prompt return of the local symptoms after so long a use of the water, from March to August. The probability is on any other assumption that the stone will be ultimately entirely dissolved.

Experiences, such as prompt relief of attacks of lithiasis, and the numerous concomitant nervous and organic phenomena, have, especially in women, been of frequent occurrence in practice.

The last case we present is that of Mr. N., aged 55 years; a rheumatic for the last fifteen years; occupation as fireman in fire department. Has had repeated attacks of acute articular rheumatism, extending into and involving the structures about joints and tendons to such a degree that the case resembled very closely rheumatoid arthritis. The last attack, and the first in which we saw him, began January 1, 1891, following a very hard night at a large fire. This attack continued with more or less severity up to June 15. He was absolutely confined to his bed, unable to move or bend a foot. There was no regular professional attendance, the patient treating himself by nostrums and etcetera. We first saw him June 18, 1891, and found the man in a miserable state. There was not a joint of his body, save the shoulders and left hip, that he could move; tissues about joints cedematous and thickened; joints more or less ankyloid; skin pale and flabby; muscles soft and relaxed; ankles and all joints of feet immovable, so that toes could not be moved; Carpus and metacarpal joints immovable, and turned to ulnar side; deformities and enlargement of phalangeal joints in both hands; no appetite; continually and freely a sickening, excessively sour-smelling perspiration was present; physically, the man was cowed and despondent.

He was ordered one-half pint of Benzoated Lithium Water (Sander's) three times a day. Diet regulated, bowels kept free, and left with the instructions that in one week he was to report to my office for treatment by static electricity; he was to get there if he had to be carried. In five days his pains had entirely ceased, and he was set up in a rocker; in ten days he was helped down stairs into a carriage and into my office. In one month from day of my first visit he was able to go on duty as night watchman in fire-engine house. This was July 18, 1891, since which time, and up to to-day, he has not lost a single night watch. The sole value claimed for the Benzoated Lithium Water in this case is the relief from pain and further progress of the rheumatic trouble by correcting at once the development and retention of the uric acid in the blood. His remarkable progress in overcoming the re-

sults of the rheumatic inflammation was due to the collateral treatment, static faradization and exhibition of the iodides, as well as the strong mental stimulus of knowing that on July 18, 1891, he must return to duty or lose his place.

Such is the record of experiences and observation which we lay before the reader, and upon which we base our plea for "known and definite quality and quantity in mineral waters." The record is the reason for the faith that is in us. The results attained are our justification in declaring for the honest, scientific, known artificial product, in preference to the dishonest, unscientific, unknown and unreliable so-called *natural* product. The rule, in the use of the latter, is disappointment and failure; in the use of the former, definite, successful results, giving profit and pleasure.

BLENNORRHOEA.

Abstract of Paper read before the Mississippi Valley Medical Association.

BY JAMES J. T. JELKS, M.D.,
OF HOT SPRINGS, ARK.,

Member American Medical Association, Arkansas State Medical Society, Chicago Medical Society, and late Professor of Surgical Diseases of the Genito-Urinary Organs and Venereal Diseases, College of Physicians and Surgeons, Chicago, Illinois.

Ricord's conclusion that gonorrhœa is a non-virulent disease has been relegated to the rear by finding the gonococcus of Neisser. All efforts to produce a blennorrhœa with ordinary pus have failed. Every effort to produce the disease with the discharge of the first stage of the disease where the pus corpuscles are few, succeeds.

The identity of blennorrhœa neonatorum and ordinary gonorrhœal disease has been established.

Neisser demonstrated the gonococcus in 1879.

His conclusions were confirmed in 1880 by Bokai and Finkelstein. These men cultivated the gonococcus and with the pure cultures produced typical urethritis.

Bockhardt in 1883 reported the results of his examinations. In 258 cases he invariably found the gonococcus. He likewise cultivated it and with the culture produced blennorrhœa. Keyser in 64 cases found the same germ.

In 1884 Zwiefel reported that only that pus which contained the gonococcus of Neisser could produce blennorrhœa neonatorum.

Bumm confirmed these statements of Zwiefel.

Sternberg, in 1884, disputed these statements of Bumm, Neisser, Bokai, Finkelstein, Bockhardt, Zwiefel, Willands and many others. With Sternberg we find Sanger, Frankel, Gervanin, M. von Zeisel and Lustgarten, and Mannaberg.

In 1886 Bumm again wrote concerning the coccus of Neisser. In numerous cultivation experiments he demonstrated the presence of this coccus; and with pure cultures of the second and

twentieth generation produced, in two women, typical urethritis and in the discharge was found the gonococcus.

This, then, is a demonstration that urethritis is a specific disease.

This specific disease of the urethra is, in a large majority of cases, limited to the anterior portion of the canal.

When the posterior is involved it should be looked upon as a complication and treated as such by cessation of all treatment of the anterior urethra and rest in bed.

You are all familiar with Fournier's celebrated statement as to the sources of infection; out of 387 cases the disease was acquired from regular prostitutes twelve times; and in 375 cases from clandestine prostitution!

Bumm's experiments with pure cultures in the eyes of rabbits has enabled us to follow the gonococcus in its travels. First they multiply upon the epithelium. In a few days they penetrate this layer of the mucous membrane and henceforth propagate within and upon the papillary layer. This process of subepithelial multiplication of the gonococcus for the first two or three weeks of a blennorrhœa is one of great importance to us; and not until the decline of the disease is this process changed to one of surface multiplication. This is a very important fact for us and explains why all our efforts to jugulate the disease have failed.

It is true that surgeons, years ago, used strong solutions of silver nitrate, 20 to 40 grs. to the oz., to abort the disease, and sometimes succeeded; but when they did it was because this strong remedy destroyed the epithelium and hence reached the coccus beneath it; but the remedy was worse than the disease.

Treatment.—I will not go over all the old remedies and modes of treating blennorrhœa, but call your attention to Prof. Stillings' experiments with Merck's pyoktanin. He used it successfully in blennorrhœa neonatorum. Last winter I heard Dr Hotz read a paper before the Chicago Medical Society giving his experience with pyoktanin in gonorrhœal ophthalmia.

By reason of the fact that pyoktanin penetrates the epithelial covering and into the papillary layer, it occurred to me that this was the remedy for blennorrhœa; and I at once instructed the attending staff in the Genito-Urinary department of the West Side Free Dispensary of Chicago to use it.

Upon my return home I commenced its use in my private practice. Some of the cases have gotten well with marvelous rapidity; a few in 24 to 48 hours. Again, others have gained no benefit from the remedy. I am not able to tell why this should be.

On June 13, 1891, Dr. George Wiley Broome, of St. Louis, Mo., read a paper before the St.

Louis Medical Society, wherein he advocated the use of pyoktanin in bleunorrhœa. His method was to insufflate the dry powder. My plan has been to use a saturated solution as an injection, retaining the fluid for five or ten minutes and by pressure forcing it down to the isthmus.

I am sure that the treatment of the future will lie in getting some remedy which has the power of penetrating the tissues and hence reach the disease germs.

NASAL GUIDE FOR THE STOMACH TUBE.

BY L. H. PRINCE, M.D.,
OF BATAVIA, ILL.

The forcible feeding of the insane through the nose with the stomach tube is frequently a most tedious operation, and in many instances becomes an impossibility, and resort is finally had to the

Nasal Guide and Stomach Tube in position for introduction.

use of the mouth-gag, so as to allow of the introduction of the tube through the mouth. As the passing of the tube through the nose, in most cases, is greatly to be preferred, the following is

offered as a simple and efficient method whereby the tube may, in nearly if not quite all cases, be quickly and easily passed through the nasal cavity and into the pharynx.

The instrument used is very similar in appearance to a small-sized urethral sound. It should be about six inches in length over all, and not more than one-eighth of an inch in diameter from the handle to the extremity, the curvature beginning about an inch and one-quarter from the end.

After thoroughly anointing the guide and tube, the point of the guide is inserted into the tube through the fenestra in the side, and passed along until it projects a little beyond the extremity. If the closed-end tube be used, which is not advisable, the point of the guide should fit into the pointed extremity. The tube and guide are then passed together into the nostril, the tube lying above the instrument, the handle of the latter being at first depressed. (See cut.) The tube is managed with one hand, the guide with the other. As the back of the nasal cavity is reached, the handle of the guide is raised, and the tube can then be easily passed down into the œsophagus, the guide being withdrawn as the tube passes over the soft palate.

The proper manipulation of the tube and guide may be easily acquired with a little practice.

CATARACT. HOW SHALL WE DEAL WITH THE CAPSULE? NEW CYSTITOME FORCEPS.

BY EUGENE SMITH, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOTOLOGY IN DETROIT COLLEGE OF MEDICINE; EX-PRESIDENT OF SECTION OF OPHTHALMOLOGY AND OTOTOLOGY, AMERICAN MEDICAL ASSOCIATION; OPHTHALMIC SURGEON TO ST. MARY'S HOSPITAL AND FREE EYE AND EAR INFIRMARY, ETC.

Local anæsthesia (cocaine) and antisepsis have been the means of producing a great revolution in the operation of cataract. Eserine, also, plays a somewhat important part. The Graefe modified linear extraction—linear incision combined with iridectomy—which has been so generally adopted as the operation for cataract, because of its supposed avoidance of iritis and consecutive destruction of the cornea, easier and better healing of the wound, etc., has, with the majority of the leading ophthalmic surgeons of the present day, been supplanted by simple extraction with a small flap (one-third of the cornea, De Wecker), and *without* iridectomy, a near return to the old classical operation, and the success of the operation is as great or greater than the Graefe method, and is in no small measure due to the use of cocaine, and the removal of all kinds of infectious factors which may exist in the conjunctival sac, lachrymal ducts, hands of operator or instruments, cleanliness and antisepsis being regarded as identical.

The adhesion to the Graefe method by some surgeons is no doubt due to a *fear* on their part, which has arisen from the *history* of the flap extraction as made in the olden time, where the flap, as suggested by Daviel, occupied two-thirds of the cornea, and was so frequently followed by suppurative of the cornea, prolapse of the iris, etc. These fears have been dissipated, with many, by statistics and experience, and I predict that ere many months, thanks to the efforts of De Wecker, Knapp, and others, simple flap extraction will be accepted by *all* ophthalmic surgeons as *the* operation, and the iridectomy relegated to exceptional cases, where it properly belongs.

An important step in the operation is the best means of opening the capsule. This feature is exciting the interest of many operators. Shall it be done with the knife while passing through the anterior chamber, before making the counter-puncture, *a la* Galezowski? Shall it be made with the cystitome, in the shape of a T, or peripherally after completing the flap, *a la* Knapp? or shall we, with a pair of cystitome forceps, extract the capsule, *a la* De Wecker, of Paris?

Each method has its advocates, but in my mind, the *beau ideal* method is the *extraction* of the anterior capsule.

With the forceps heretofore in use, this has been a difficult procedure, even in the hands of experienced and dexterous operators, because of the danger of catching a fold of the iris between the blades, and the danger of bruising the flap by the necessary *tilting* of the forceps in order to engage their points in the capsule.

De Wecker, who first suggested removal of the anterior capsule, has forceps made with one or two sharp teeth placed near the points of the blades, but on the *under side* of the blades, after the style of the iris forceps of Leibreich and Mathieu. Knapp modified with more teeth and a slight separation of the blades to prevent catching and bruising a fold of the iris, the points of the sharp teeth being slightly directed downwards or backwards, to better seize the capsule, but owing to the necessity for tilting the blades backward into the pupillary space, their use for this purpose was nearly or quite discarded. Experiencing these difficulties, I sought to overcome them, and have succeeded to my own satisfaction, as I have demonstrated by their use in private, and before my class, in many cases.

My first forceps were simply a modification of Knapps, with four fine, sharp teeth on one blade

and five on the other. These I further modified by having three teeth and four teeth only, and having *only the points of the teeth* sharp, that they may sink into and *tear*, not *cut*. The principal modification, however, is the curving or dropping downwards of that portion of the ends of the blade which contains the teeth, below the plane of the blades, that the teeth may set down into the pupillary space *without tilting* the forceps. The forceps being introduced closed, as for iridectomy, the end of the forceps is pulled forwards till the curved portion, containing the teeth, is in the pupillary space, when the blades may be allowed to open to their full extent beneath the pupillary border, and by gentle pressure against the lens, the capsule is seized and more or less forcibly (within reason), by a little sudden twitch, extracted. The curve where the teeth are dropped is 1 mm. in depth, the part containing the teeth is 2 mm. long, the blades open automatically 5 mm., and the blades when closed, except that portion containing the teeth, are $1\frac{1}{2}$ mm. apart.

The forceps are most admirably made by Shepherd & Dudley, of New York, and the accompanying wood-cut affords a good general idea of the instrument.

130 Lafayette Ave., Detroit, Mich.

SUBSTITUTION AND ITS ATTENDANT EVILS.

BY JOHN AULDE, M.D.,
OF PHILADELPHIA, PA.

The evils attendant upon substitution and sophistication of remedial agents have long been surmised; they have not, however, until recently, received attention at the hands of the medical profession. Increased diagnostic skill, along with greatly improved facilities for the manufacture of medicaments, favor an approach toward mathematical exactness in computing therapeutic results. When these are wanting we challenge the character of the remedy. The question which presents itself is: Has our patient received the true medicament or a base counterfeit? However attractive in theory, it will be found impractical for the medical profession to drift away from the pharmacists, and it should be our aim to reward the faithful and bring the guilty to punishment. The friendly bond between the two professions should be honesty, as neither can afford to work independently; there is an interdependence which makes them mutually helpful.

It is said of Lawson Tait, that he has returned to first principles, and carries a mill with him, so that when ergot is needed, he prepares it fresh with his own hand. The reliable character of Squibb's ether has been maintained through his business sagacity in having it prepared chemi-

cally pure and distributed all over the world in sealed cans, thus precluding the possibility of sophistication or substitution.

The life of a patient suffering from rheumatism may depend upon his being supplied with sodium salicylate prepared by a combination of Merck's chemically pure bicarbonate of soda and true salicylic acid obtained from oil of winter-green, and yet few pharmacists, even in large cities, pretend to keep either in stock. They are the exception in Philadelphia, and doubtless the same is true of other cities.

Some years ago Dr. Squibb, of Brooklyn, set his seal on Marchand's peroxide of hydrogen, by endorsing its character and defending its merits as the most powerful and yet harmless bactericide which could be employed in the treatment of various formidable and fatal diseases. Dr. Robert T. Morris, Dr. Paul Gibier, and other well known authorities have corroborated his statements from clinical observation, and as a consequence, a revolution has taken place in our methods of treatment in both medical and surgical practice. The efficacy of this simple remedy, its innocuousness and extended field of application, have shed a flood of light upon modern therapeutics, but at the same time there has followed in its train a host of worthless imitations.

The substitution of the commercial for the medicinal peroxide is calculated to work serious injury and destroy our confidence in a most potent remedy. In the treatment of diphtheria, for example, the commercial product is positively harmful. When death results, shall we blame the attending physician or the unscrupulous druggist who substitutes a base imitation for the genuine product? And still, pharmacists who claim to be respectable, do not hesitate to trifle thus with human life. Is it any wonder then, that our mortality percentages are on the wrong side?

Cascara sagrada has been counterfeited and sophisticated until it is almost impossible to secure a reliable preparation of this most useful medicament, although Parke, Davis & Co., the pioneers in its introduction, have adopted every means in their power for the protection of the medical profession. Antipyrin, a patented preparation, has met with phenomenal sales, and possesses distinct therapeutic properties, and as a result, imitations and substitutes are offered to take its place in medical practice. Whether these imitations are better or worse than the original product, I do not care to discuss; neither is it for the druggist to decide. The decision here, as to any special remedy or preparation, rests entirely with the physician, as he alone is responsible for the condition of his patient; no one else, not even the druggist, should be permitted to interfere with his directions. Substitution is an

evil which should be guarded against; it is an evil which must be eradicated, or the entire medical structure will collapse. It is a duty we owe to ourselves and to our patients to look after this unnatural condition of affairs in which we are so vitally interested, and the time is near at hand when a systematic effort must be made with a view to accomplish the desired end.

This subject is commended to the attention of the American Medical Association, with the suggestion that a committee be appointed who shall recommend suitable measures for the protection of the medical profession from the evils of substitution and sophistication on the part of unscrupulous pharmacists. Shall we have a "list?"

4719 Frankford Avenue.

KANGAROO TENDONS.

[At the annual meeting of the Association of Obstetricians and Gynecologists, held in New York in September, in the discussion upon suture material, Dr. Henry O. Marcy, of Boston, advocated the use of kangaroo tendons, and the interest in the subject is so general, that we reprint the following from the volume of Transactions now in press.]

I take pleasure in exhibiting, at the request of some of the Fellows, samples of kangaroo tendons, in the condition in which they are sent to me from Australia. It will be noted that this animal has the tendon of the tail disposed in a bundle of parallel fibres, running its entire length. These vary in size, dependent upon the size and species of the animal. As will be observed, they are easily separated into even, smooth, round strands of uniform size. Those from the species called the wallabee are preferable, since the size of the tendons is that more commonly desired for the suturing of wounds. They vary somewhat in length, averaging about 20 inches. I have carefully studied the tendons of every animal which I thought could furnish the material suitable for sutures.

The Indian of the Northwest still uses as thread for domestic purposes the fascia lata of the moose, which is sun-dried and maintained dry until wanted for immediate use. It is not unlike the fascia lata of the buffalo, which from time immemorial, until quite recently, has furnished an ample supply. It is almost identical with that of the reindeer of Northern Europe, which is still largely in use there as a suture. Tendons of this character have furnished me, in part, suture material for surgical purposes for the last ten years. They are, however, very inferior to kangaroo tendon sutures. The only other animals which I know that have tendons similarly disposed are the common rat, the squirrel and the opossum.

Dr. C. E. Mastin, of Mobile, sent me recently specimens from the tail of the opossum which

furnish excellent suture material, but they are, unfortunately, only 10 or 12 inches in length.

I sent to Australia more than ten years ago for a supply of tendons from the tail of the kangaroo, inferring from the relationship of the species with the squirrel and opossum, that the tail of this animal should furnish similar tendons, and of course much longer and larger. It has been only after many and repeated efforts that I have been enabled, within two or three years, to secure a supply much in excess of my own immediate requirements. In earlier years I have paid any price demanded, even in Australia, 60 cents per strand, by the hundred. However, an arrangement has been recently effected, by which an ample supply may be obtained for furnishing the entire profession with reliable tendons. They are prepared ready for use, under my own personal supervision, at a cost of \$10 per hundred. These are kept by Messrs. Codman & Shurtleff, the well-known instrument makers of Boston, from whom they can be obtained, or, if preferred, by sending directly to me.

At this price the cost is not much in excess of well selected and properly prepared catgut, to which it is in every way greatly superior.

The tendons are taken from freshly killed animals, are quickly sun-dried, and kept dry until ready for preparation. They are then soaked soft in a sublimate solution (1-1,000), carefully separated, sorted, and quickly dried. They are then immersed in ether for twenty-four hours, although this seems hardly necessary, as they seem to be absolutely free of fat. After this they are chromicized and permanently put up in a solution of carbolic acid (1-10), after the Lister formula for the preparation of catgut. They should be retained in the carbolic oil until required for use, then wrapped in a towel, wrung from a 1-1,000 mercuric solution, for a few minutes, which makes them supple and easy of application. They do not soften and swell as catgut similarly treated. It must, however, be remembered that every precaution of modern surgery is demanded in placing *aseptic* buried sutures *aseptically* in *aseptic* wounds.

I have experimented in the preparation of suture material, in the various ways advocated by a number of authors. I have found none so trustworthy as the chromicized suture, permanently kept in carbolic oil. I quite prefer not to use it until after it has been prepared for six months and it appears to improve with age. In the larger sizes, in well sterilized tissues, it can be demonstrated after three or four weeks, and a marked thickening of the tissues is observed along the line of the buried sutures for a considerable period longer.

Catgut has many defects, chief of which is that, for days together, the intestines of the animals, from which it is made, must remain in a

state of active putrefaction, in order to separate the connective tissue sheath from the other coats of the bowel. This is then subdivided as required in size, and twisted into a thread, the ordinary catgut, or violin strings of commerce.

The sterilization of this material, so as to render it safe for sutures and ligatures, and yet not injure its integrity, is by no means easy. As has been shown by many observers, the larger sizes especially of catgut, prepared for surgical use, contain bacteria capable, under favorable circumstances, of reproduction. This is doubtless the most valid reason why catgut, as suture material, has fallen into disuse.

When its histological elements are investigated, it will be seen that its ultimate fibres cross each other diagonally to the long axis of the bowel. This is an admirable disposition to allow of the ever-varying size of the intestine, but it is little suitable for the purposes of great strength and inelasticity. The illustration is not overdrawn in the comparison of the attempt to make a strong cord by cutting the finest woven fabric upon the diagonal and twisting it. So great is the strength of the connective tissue of animals that catgut, when kept dry, is capable of resisting great strain, as in the high tension of musical instrument strings. But, when macerated, a softening process which must take place in the tissues of the body, the catgut unfolds and becomes a soft, elastic material. This explains why, in the interrupted suture, the knot is so untrustworthy. The tendons proper of animals have their fibres uniformly disposed in parallel lines, and as a consequent, when moist, are many times stronger than the same size of catgut.

Under the most favorable circumstances, sterilized silk sutures disappear far too slowly; and for this reason, if used in any quantity, must generally be applied in a manner to permit of removal. When buried within the tissues, they are more generally encapsuled, rather than absorbed, and often, even after many months, produce irritation and are thrown off as a foreign body.

A properly prepared, aseptic animal suture, buried aseptically in healthy tissues, slowly disappears, and, as histological studies abundantly prove, they are replaced, in large measure, by connective tissue cells, making a band of living, constricting, or supporting structure, which surrounds the included part.

This is of the highest importance in the ligating of large vessels, and of almost equal value in the supporting of many of the structures coapted in wounds, as, for example, in hernia, the repair of the perineum, etc.

I am certain that one of the greatest advances in modern surgery is found in the immediate coaptation of all well vitalized aseptic wounds, hermetically sealed without drainage. For this purpose, the tendon suture is the ideal material,

and I hazard very little in predicting that, at an early date, the clumsy, bungling method of closing wounds with interrupted sutures, at best liable to infection and subsequent danger, will be relegated to history, and the tendon suture will become an indispensable factor in wound treatment.

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

First Annual Meeting of the Electro-Therapeutic Association, held in Philadelphia, September 24, 25 and 26, 1891.

(Continued from page 806.)

FIRST DAY—AFTERNOON SESSION.

Dr. A. D. Rockwell, of New York, then read a paper entitled

ELECTRICITY IN AMERICA,

dealing more especially with the earlier work of his late associate, Dr. Geo. M. Beard, and himself in developing the field of electricity in medicine, and in securing for it professional recognition. He said that twenty-five years ago electricity was but another name for quackery, and to devote especial attention in that direction was a plea of guilty to the grossest ignorance and fraud. As an illustration of this, he referred to the fact that when he first ventured to present for the consideration of the Medical Society of the State of New York a paper on the Medical Use of Electricity, an eminent physician on the committee exclaimed, What! is he regular? The whole subject at this time was a veritable *terre incognita*. Medical journals seldom referred to it in any way; it was not mentioned in our schools, and of American literature along this line there was substantially none. Electricity was known to be of virtue in stimulating muscular contractions, and paralysis was the main, if not the only, disease in which this agent was especially indicated. Abroad, localized electrization had been worked up by Duchenne, Remak and others, and in proportion as their knowledge in regard to the whole matter was limited, in just that proportion were most of the followers of these two leaders dogmatic in the assertion of their beliefs.

One party preferred the galvanic and another the faradic current, and a long and unreasonable controversy arose, mainly in reference to the question whether the better therapeutic effect was obtained by applications to the motor points or to the muscles themselves. When, therefore, Dr. Rockwell and his associate, Dr. Beard, asserted and demonstrated that electrization was something more than a mere stimulant; that it was a

tonic of very remarkable efficacy, and as such was indicated in a wide range of diseases associated with debility and impaired nutrition, the medical press here and elsewhere gave to the subject the most careful consideration.

In Germany especially, through the careful *résumé* of Prof. Erb, of Heidelberg, the ideas advanced were received with much interest and appreciation. Dr. Rockwell referred at some length to the methods of general faradization and central galvanization, the revival of the use of static electricity, and the use of electricity in gynecology in this country.

He laid especial stress on the value of electricity in the treatment of extra-uterine pregnancy—a suggestion entirely American, and deprecated the prejudice that decried the method in those early cases where it was applicable, in favor of the knife. He regarded the future of electro-therapeutics as assured, and remarked that the tardy fulfilment of the promises of its youth had been due not so much, perhaps, to the prejudice of men of science, as to the necessary mechanical difficulties in the way of its employment, and to a want of knowledge of the indications for its use and the method of making the applications.

Dr. Morton: If no one is going to say anything, I rise to express the general feeling of pleasure we have in this historical account of electro-therapeutics, of canonizing that period which electro-therapeutics in this country has passed through, and its various manifestations in France and Germany. I recall, at about the same time you speak of, the work of Golding Bird, Wilkes and others. That of Bird of 1840 is still a very remarkable work, and will repay reading by any one. His results were very remarkable.

While on my feet, and although I rose simply in recognition of the great merit of Dr. Rockwell's paper, and acknowledging there is little to go over in his paper, as his statements are very general in their nature, I will in the most courteous nature, say that his placing so much emphasis on general electrization is not what we are after. We want to localize and specify treatments. I see no more reason to attach a particular name to general faradization than to general bathing, or anything which helps health in any way. I think in regard to central galvanism that the reader should be more definite in his statements as to the conditions in which central galvanism is most applicable.

Dr. Blackwood: I have operated on thirteen cases of extra-uterine pregnancy, each of which has been diagnosed by at least one eminent gynecologist. The reason why I prefer faradism, which I use instead of galvanism, is on account of its peculiar action. It acts on the muscular fibre, and it appears to me to be of the same nature as the current in electric lighting. Up to

the last seven months I had no particular proof of my supposition, but as I had always used the faradic current, I have taken special pains to observe its action, and in gaining facts to support my theory. I have some very interesting experiments which I have performed, besides one or two specimens, and I have thirty products of conception, all of which are not more than three months, and so far as my judgment is concerned, I think I am correct as to the mechanical effect of the two currents. That is, the faradic does destroy the integument. I use the faradic current for one hour, and endeavor as far as possible to get the embryo as closely in the embrace of the electrode as possible. After using the faradic I then use the galvanic, 70 to 100 milliamperes. I use galvanism for absorbing the foreign body, as our opponents claim it. I say this without the slightest idea of criticising the gentlemen who have spoken, and in order to combat what may seem adverse criticism, I wish to say that for the last ten years I have obtained the best results from the central treatment, and I think it is the best way to overcome obscure nervous affections. But I often depend on localized treatment as Dr. Morton has claimed, and I think we get good effects from both central and general methods.

Dr. Rockwell: I cannot see why Dr. Morton's remarks apply, I only believe that the doctor has had very little practical experience in following out the methods which I and others have found of the utmost value. Why we should not have a certain name for a certain method, to indicate what it is, I can't see.

Augustin H. Goelet, M.D., read a paper on

THE ACTION AND APPLICATION OF THE FARADIC CURRENT IN GYNECOLOGY.

In presenting the paper, the author said he desired that the discussion would throw more light upon the subject, which was surrounded with much uncertainty and obscurity. The action and application of the faradic current in gynecology was, to his mind, one of the greatest problems of the day in medicine. The literature of the subject was, unfortunately, exceedingly confusing in regard to many important points in connection with this current as derived from the secondary coil. This was regarded as particularly unfortunate, because the faradic current was a therapeutic agent of too much value to be neglected or discarded, as it has been by some of the workers with this agent. He regarded the imperfectly constructed apparatus as the cause of the indifferent results which have been obtained by different experimenters. The construction of secondary coils has heretofore been looked upon as such a matter of indifference by physicians who use them that the manufacturers, having no guide for their construction, have suit-

ed their own convenience in the matter, regardless of any physiological effect to be derived therefrom. In consequence these coils, in the ordinary apparatus, will be found to vary from No. 15 to 26 wire, and from 60 feet to 200 yards in length. Experience had led him to declare that the faradic batteries of ordinary construction are totally inadequate for gynecological work, and satisfactory results cannot be expected from their use. The uncertain statements of manufacturers regarding the length of the wire composing their secondary coils, led him to advise those who desire to be accurate, to measure the resistance of their coils, and calculate the length for themselves, instead of depending upon the statements of the makers. The Englemann battery, with three different secondary coils, he declared to be the only reliable apparatus suitable for gynecological work manufactured in this country. In this the coils are arranged as follows: The secondary coarse wire coil is of No. 16 wire, about 75 yards long; the intermediate is of No. 22 wire, 225 yards long; and the fine wire coil is of No. 32 wire, about 660 yards long. Though these coils were to be regarded as a great improvement upon others, they do not wholly meet the requirements of gynecological work, since very sensitive conditions cannot bear the current from his finest coil. Therefore the following arrangement was suggested, viz.: One spool should contain 1,500 yards of No. 36 wire, which if tapped at 1,000 yards would give two additional coils, one of 1,000 and one of 500 yards in length. Then another coil of No. 32 wire 800 yards long, tapped at 500 yards, would give a coil of that length, one of 300 yards and another of 200 yards. Then another coil of No. 22 wire, 250 yards long, to correspond with Englemann's intermediate. There should also be a coarse wire coil of No. 16 wire, about 100 yards long. By this arrangement practically eight different coils are secured, and a corresponding variation of the current, there being but four spools. It would be possible by this arrangement to treat very sensitive conditions, which could not be approached with the other coils.

Arguments were adduced and experiments given, showing conclusively that there is a marked difference in the effect of the current as derived from coarse and fine wire secondary coils, and also in different lengths of the same size wire, which has been denied. The current from the coarse wire coil was declared to be a current of volume or greater ampèrage, as distinguished from that of the fine wire coil, which is a current of tension or greater electro-motive force, the former being useful for muscle stimulation and the latter for nerve sedation. The failure to obtain satisfactory results with this current was attributed to the imperfect and variable construction of apparatus by different manufacturers.

The use of a rheostat or controller in the secondary circuit, it was declared, did not sufficiently vary the physical conditions of this current to make one coil suitable for all purposes, as has been claimed.

The construction of the vibrator or current breaker was regarded by the author as a point of much importance. This device upon the ordinary faradic apparatus produced interruptions entirely too coarse, and the movement is uneven and irregular. He called attention to the fact that for producing sedation from the fine wire coil, a maximum rapidity of interruption should be obtained, and that there should be not 50 or 80, as is usually the case with the ordinary apparatus, but 100 to 200 per second. Coarse interruptions are more stimulating and irritating, and fine interruptions are more sedative. The importance of using coarser vibrations for the coarse wire coil and finer vibrations for the fine wire coil was emphasized. The current from the coarse wire coil is used for muscular stimulation, and that from the fine wire coil for sedation. In applying this current for stimulation for the muscle, it is desired to produce an alternate contraction and relaxation which will resemble the normal physiological action, and the interruptions must be slow, so as to allow the muscles time to respond in a normal manner. That is, sufficient time must be allowed between the interruptions to allow the molecular changes to take place. Slow interruptions permit contraction and relaxations to occur, and the normal physiological action is closely imitated. In effecting sedation, it is desired to paralyze the sensory nerves and wear out and relax the muscles, thus relieving the painful contractions, and the interruptions must be fine. When the interruptions are rapid, the muscles are unable to respond to every vibration, and constant contraction or a tetanoid condition is produced, which eventually wears out their contractile power, and consequently a condition of relaxation is produced if the application is continued long enough. Likewise this constant and intense stimulation of the sensory nerves results in a temporary loss of their power to respond, and a condition of anæsthesia is brought about, which is more or less prolonged according to the duration and frequency of the applications. Attention was called to the fact that sedation was secured by a prolonged application of the current, from ten to twenty minutes. The duration of the application of the current from the coarse wire coil should be limited to five minutes. In all applications where sedation is desired, the strength of the current must be increased very gradually without jerk or shock, and it should be decreased in the same manner.

The effect of the current upon the vaso-motor nerves and the capillary circulation was also referred to, and it was claimed that thereby blood

stasis is relieved, and the absorption of effete products is hastened.

The polarity of the faradic current was insisted upon. Though usually regarded as a to and fro current, it is certainly endowed with polarity, since experiments show that there is a distinct difference in the physiological action of the two poles. This, it was explained, is due to the fact that through the high resistance of the human body, only the break current had a perceptible action, the make current being cut down to such an extent by self-induction as to make its action inappreciable as applied to human tissues. Hence the faradic current, when used upon human structures, may be said to flow in one direction, and is not an alternating but an interrupted current.

Attention was directed to the fact that the best effect of the secondary current is obtained only when the secondary coil completely covers the primary; that is, when the whole of the secondary coil is receiving the full amount of induction. In order to secure this from the beginning of the application, and at the same time make it bearable to the patient, a rheostat or regulator is placed in the battery circuit. This regulator is composed of fine German silver wire, of proper length to afford sufficient resistance to operate six Leclanche cells arranged in series. It is a very simple device which gives the operator perfect control of the current, and allows it to be graduated to suit any case. The increase or decrease of the secondary current is regulated by increasing or diminishing the strength of the current in the battery circuit by means of this regulator, which interposes a variable resistance. The method of operation consists in applying the electrodes with the secondary coil removed from the primary, then allowing just sufficient current to flow through the regulator in the battery circuit to operate the vibrator smoothly but feebly at first, and the secondary coil is then slowly moved up until the primary is completely covered. The strength of the current is still further increased by allowing more current to flow through the rheostat or regulator until the desired intensity is reached. Applied in this way, the very best effect of the secondary current is secured from the beginning of the application, and the most sensitive conditions may be brought under its influence, such conditions as could not possibly be treated in the ordinary manner with the best effect.

The clinical capabilities of the faradic current as derived from properly constructed apparatus, and the therapeutic indications, he thought could be readily inferred from what had been said, and it was, therefore, unnecessary to go into details regarding the respective indications for sedation or muscle stimulation. The different physiological effects of the interrupted induced current as derived from differently constructed coils being

recognized, the way is comparatively clear. It was, however, stated that acute inflammatory process was amenable to treatment by this current under suitable conditions of high tension, as when it is derived from a coil of very fine wire of great length, if a maximum rapidity of interruptions with perfect smoothness is secured, the effect being obtained by restoring the equilibrium of the circulation.

President: Before the discussion on the paper just read, I wish to announce that there will be another meeting to-night at 8 P.M. The paper is now open for discussion.

Dr. Bigelow: It is rather difficult to make a discussion of such an elaborate paper as this. I, in my writings, time and time again, and in a book recently published by me, brought out the distinction between primary and secondary coils, which were first insisted upon by Duchenne and at Apostoli's clinic in Paris. I am not a sufficient physicist or mechanic to go into the physical aspects of the question, for there are such questions. Clinically speaking, there is a very marked, decided and important difference between primary and secondary currents. The current from the secondary in all cases of ovarian troubles is the only current which will be tolerated. I have seen cases of ovaritis, characterized by very persistent and aggravated pain, yield at once to applications of the secondary current. I have seen it aggravated to a degree unbearable by the primary current. I have twice, in some of my experiments lately, seen it yield more rapidly to the static, which is more like the faradic. The feel of the secondary faradic is very pleasant, and from my experience in gynecology, as a sedative it is very marked. It is not used as much as it ought to be, although it is much more used now than formerly.

Englemaun, of Germany, has had some remarkable results in the use of this current. It is a much less muscular stimulant than the primary. You do not get any perceptible effects from the secondary coil on the muscular system, so that it seems to me that there should be a distinct and decided difference between the two coils, depending upon the manner of generation, as it is entirely different. With all the facts in these cases before us, in cases of pain in fibroid tumors, and in conditions of intra-uterine fibroids, I think the faradic current is the best.

Dr. Hayd: I am sure that every one has had great pleasure, and has derived very much benefit, from listening to this valuable paper. Those of us who have had clinical experience are satisfied that the faradic current is sedative in its properties, and the question now presents itself, How can we get the sedative properties necessary in our ordinary practice? Those of us who have used the currents with the purpose of getting muscular contractility have found that the

womb does remain contracted permanently. To make this applicable in acute conditions, as in acute reflexes, and where there is extreme sensibility, and where, after one application, so much relief has been given that the woman could go to work and attend to her other duties.

There is one good thing which is suggested to me from Dr. Goelet's paper, and that is this, that the president should appoint a committee of three who are sufficiently qualified to make tests on this subject, to study and observe results, and report at our next meeting their experiences with the differences of the coils, and by that means we will be able to make a standard rule whereby these faradic applications can be made. I do not know that there is any particular difference between the two poles of the faradic battery physiologically; there may be, but I am satisfied we can relieve pain from either pole, whether positive or negative, and whether one has a more sedative property than the other I do not know. The longer I use the fine wire, which I saw used while in Paris, the more I am satisfied the fine wire is capable of giving relief; and yet it is only about 320 yards in length; another was 1,000 yards long. That it would enable us to go into acute conditions where at present I am afraid to go I can't say.

Although I find that it is a great sedative, my experience suggests that it is also capable of doing great mischief. Take it in sub-acute inflammation: I have lighted up inflammations and made great trouble by a weak current of a few minutes' duration. As I speak I recall a young woman of highly nervous organization, delicate fibre, delicate skin, long eyelashes and eyebrows. She complained of some pain, and, on examination, there was tenderness in both inguinal regions. Her temperature was not more than $99\frac{1}{2}$ at any time. After three or four days' treatment with ordinary hot douche and bromide of potassium, I resolved to make an application of the faradic coil. I relieved the pain somewhat, but after a while she suffered a good deal, and that night I made an examination, and I detected a swelling, which gradually increased in size, and there was, at the end of three days, a great mass filling up the posterior cul-de-sac. And I made up my mind I had developed a hematoma.

Dr. Hutchinson: I am exceedingly in favor of the secondary current of Faraday. All I know of the faradic current was learned from Duchenne, and that is probably why I use it, as I adopted his ideas to a large extent. So much do I believe in the secondary current, that I have a large coil of some miles of wire, made so that the primary current can be reached, and the secondary coil is an enormous one. It is tapped at various points, so that it can be increased or diminished in force at will.

I do not find, and I have not found in a good

many years of practical work, as Dr. Goelet says, any difference in the faradic effects of one pole or the other. I do not know of any. I do not get any difference in the effects or in the results even with the use of this great secondary coil. Sometimes I use as much as a mile of wire, and have used more in cases of anæsthesia. I do not find any difference between the poles. What is done in gynecological work I do not know, but that is the practical result of years of use of this great coil, as far as the negative and positive poles are concerned.

I believe that a certain number of feet or yards of wire have a different effect on the circuits through which it connects. There is no question about this. There is none in the induced current. I do not believe it can be made with the utmost force of the great Rhumkorff coil which I use. In the coil which I use you can get a great spark twenty-four or twenty-five inches in length, and that, of course, means great force.

Dr. Von Raitz: I don't exactly understand your paper. Do you intend to produce a secondary current for sedative effect?

Dr. Goelet: Some speakers have misunderstood me. Take a battery where the secondary coil is movable. Dr. Bigelow has spoken of the secondary coil as the primary. In gynecology I seldom use the primary coil, and have alluded only to the two coils above the primary, both being secondary coils, the coarse wires being stimulant and the fine wonderfully sedative.

Dr. Von Raitz: What I have done in gynecology I have tried to get a real basis for. I have applied the currents to the living and dead body, and have analyzed cases as they have presented themselves. From what Dr. Goelet has said, there is no doubt but that the faradic current has an analytic effect on tissue, and if you look for a reaction, the positive pole shows some acid reaction and the negative alkaline reaction. If that is the case, and there is no doubt of it, and if the faradic current is not properly used, much mischief can be done. That is because there is an effect in the faradic current, and it is no play work.

I have had a patient I treated for ovarian abscess and some pelvic adhesions. I wanted to find out what the faradic current would do, and I have experimented some time and improved her condition, but not sufficiently, and then I went to the constant current. The faradic primary current has a stimulating effect. The secondary current, the finer the wire and the quicker the vibrations, the greater the analytic and sedative effect. But at the same time the faradic current has an analytic power to a less degree, but in some acute inflammations it should not be used at all.

Dr. Walling: Perhaps some of the effects in

these conditions are due to the rapidity of the vibrations more than to the coil used. That may be so, however. My own experience in using the secondary coil is to throw the whole coil in and take my current from the rheostat, and I have found that this is the better plan. I get better effects from it than I do by attempting to take a part of the coil, for there you get the whole effect of the primary on the secondary, and then you gain more from the rheostat.

As to polarity of current, it has been my custom to distinguish between the two, and I think we get different effects. I am open, however, to conviction on this point. I have found, in many cases, at least, the positive to be more sedative in its character than the negative, yet I believe both will relieve pain.

Dr. Morton: The paper suggests a great many points, and is difficult to discuss, but I will confine myself merely to one or two points which relate to the polarity of currents and the effects of the current according to the lengths of the wires. I wish first to make this point, that there is a good deal of misunderstanding in our talk about the faradic current. We say faradic current, and we don't make plain in that instance whether we are using the interrupted or the alternating current; that is what we should clear up before questioning the difference between the currents. The primary is an interrupted, and we speak of both as alternating currents, and we should make a distinction before giving the subject further discussion, and confine ourselves to the point referred to by the reader of the paper. Is it to make a distinction between primary and secondary currents and finer and coarser wires? I should be very glad if a motion is made directing tests, so that manufacturers could be instructed how to make a standard induction battery, a standard coil, a standard length of wire, and then we would be on a standard basis to begin clinical studies. And that brings me down to what I want to say respecting the different effects, as reported by different observers. There has been the greatest difference in the character and length of the secondary coils. There is our friend from Providence who uses a mighty Rhumkorff coil and gets no polar effects; and there is our friend from New York, with only a short wire, who gets effects. I think they are both right. There is a difference in construction. As Dr. Goelet points out, as you increase the number of coils, you increase the voltage and force. A current which has a section of two, three or six hundred turns is entirely a different matter. As Dr. Gordon says, in his careful measurements, the induction current, the secondary current of the break, measures thirteen times more in intensity than the same current of make. So we see that the make of the primary exerts its entire influence in charging the coil of the secondary. If the

current of the break is thirteen times greater than the current of the make, than one of those impulses is thirteen times stronger than the other. You can see one end of the line will do thirteen times more electrolytic work than the other; but I do not agree with the reader of the paper that the current intensity of the make is not sufficient to penetrate the human tissues. Here is an interesting point. If the electro-motive force of the make secondary is not sufficient to penetrate the human tissues, we are not treating disease by the alternating current at all, but the interrupted current, which gynecological men do not use at all, and it all comes back to this same point, that we must have a standard induction coil. I can go to an instrument maker and have him make me two hundred turns in my secondary coil which will give me an interrupted current, and not an alternating at all, so the whole question simply resolves itself into the construction of the secondary coil, and before any clinical observations are made, which are bound to be contradictory as the mechanisms are different, I think there should be some uniformity as to the kind of machine to be used electrically.

Dr. Waite: Speaking of faradic coils, as Dr. Goelet has remarked, all manufacturers have made them to suit themselves, and they make them to make as much noise as possible. I am inclined to think to get at the proper coil it is necessary first to make a proper primary and then a secondary. The number of vibrations has a great deal to do with the sedative effect of the primary current, for the reason that if you have a slow vibration you only have a small number of impulses, but if it is very rapid you have a large number, and in that way you have as many times more electrical currents as vibrations. It would be a good plan for a number of physicians to investigate the matter and decide upon such a coil as would fit, both in the external dimensions of the primary and the size of the soft iron core, and also the size and length of the secondary coil, and it can be only done by experimentation. There is no rule laid down for making coils.

Dr. Massey: This problem is of a technical character which interests us as practical workers very much. Very little can be done until we get a meter to measure the faradic current, for the whole question at the present time is in much the same condition as was the galvanic current prior to the invention of the milliampère-meter. You all remember the absurd discussions we heard when we were ignorant as to the relative value of large and small cells and a small and a large number of cells, all of which were buried very deep when the meter was devised. So here I say if we can know what we are talking about we could discuss it intelligently, and we cannot know until we have a meter to measure the faradic current.

The paper of Dr. Goelet was exceedingly interesting and showed a remarkable grasp of the subject. He surprises me very much, however, when he states that he does not use the primary current. That is a current I discarded some years ago when engaged entirely in neurological work, as I could find no difference except weakness as compared with the secondary. Since I have been using the primary current in gynecological practice, where we have low resistance with large poles, I have found it extremely valuable, and this is simply because it is inefficient if the resistance is high. As Dr. Martin has pointed out, it is simply an interrupted current. With it I can get marked contractile effects, in myomas, and I get better contractile effects in the abdominal and intestinal walls than when using the secondary. Large poles with a minimum of resistance are necessary.

The variation between the primary and secondary currents used in this way is extremely remarkable. Patients who feel no contraction from the secondary current can't stand one-quarter part we can give them from the primary—why? Partly at least because it is in one direction, but more because we have greater amperage, and we get more amperage provided we have small external resistances and a coarse wire; for after all the differences of most resistances within the coils would matter little when you have two or three hundred outside of it.

As to the effects of a coarse wire as a secondary coil I must plead ignorance; I have not used it. I think Dr. Goelet may have made a good point against me there; for what a current will do with a mucous surface and low resistance is not to be compared with what it has done with high resistance, as in the skin. This question was at one time decided by me against the claims of a coarse secondary coil on account of a failure of such a coil to send a strong current through small poles and the skin of the forearm. This, I acknowledge, was an insufficient and incorrect experiment. The coarse wire had to be carried almost all of the way over the core to produce the same effect as the secondary did with about one quarter covering the core, doubtless on account of the resistance in the external surface. In spite of the grasp of the subject shown by the reader of the paper and the remarks here, I do not feel that this thing can be decided until we can measure our current. We can learn something from what we do in clinical work, but I do not think it will settle the question to get a standard of anything, as we cannot keep standard cells in order. Such standards will be worthless as exact measures with an actuating cell that varies in power from time to time, and I have not yet found a cell that will not.

Dr. Goelet: Dr. Morton expresses very forcibly my idea in bringing the subject forward at

this meeting. It was that we should have uniformity. If we can do that, we can agree. There is no doubt but that the faradic current, as we employ it to-day, is merely an interrupted and not an alternating current. We do not get the effects of the one-thirteenth which Dr. Morton speaks of, but the effect of the plus, that which is in excess the amount of the break in excess of the make current.

As to the remarks made in regard to measuring the current, I believe that Dr. Wellington Adams has invented an instrument to measure the faradic current—I have not seen it, however,—and if he has made it, it is simply to register the surplus of one of these currents over the other. He is not measuring what effect we are producing on the patient, the amount of voltage or amperage, but merely the excess of the break over the make. Still, I am not familiar with his instrument.

Dr. Walling suggests that there might be a more sedative effect in the rapidity of the interruptions rather than a sedative quality, and I drew attention to that in my paper. The more rapid the interruptions the more sedative the effect.

I have said that the primary was not used in gynecological work, because I have not used it, and I do not know of any one except Dr. Massey who has. It is more contractile. Apostoli does not use it, he always uses the fine or coarse secondary and I took my cue from him.

Dr. Massey spoke of not believing in the difference of effects of the two classes of fine and coarse secondary coils. He found that it produced a similar effect when they covered the primary to a different extent. That is, that the coarse wire coil had to be all the way over the primary in order to get the same effect you do from the fine wire coil. Of course that is so. When you have it covering you have less of volume and little force, and in order to increase the force you must slide more over the primary, you expose it more to the influence of the generating cell; therefore to obtain as nearly the effect from the coarse wire coil as you would from the secondary you slide more over the primary, but you cannot get the same effect where the resistances are equal.

If you apply the two currents to resistances like the skin by small electros, one over the hand and another far away at some indifferent point, your current from the fine wire will produce a better contraction than the coarse, as you have more current. Still if you cut down the resistance in the skin and make it little or nothing, as you do when you take both electros in the hand, or as you do in the vagina, then of course the electro-motive force is not so necessary. You do not get the same muscular contractions as with the coarse wire coil.

Dr. Bigelow said he did not think the secondary coil was used very much; it is not, I wish it was; it is too valuable to be lost sight of, and I think it is because it is so little understood that it is not used more.

Dr. Morton has explained clearly my idea of the difference of high resistance coil, and it is not necessary for me to reply to Dr. Hutchinson's remarks.

Dr. Hayd has made some use of this current foreign to my experience. I have not had sufficient experience to agree with him. He claims that in cases of recent injuries you get better effect from the coarse wire coil than from the fine wire coil. Now in this case of Dr. Hayd, he don't know what injury he has produced before using the current. Perhaps Dr. Englemann may have produced irritation. And he claims, in recent venous engorgement, to get more irritation from the fine wire, and this makes plain the case of Dr. Hayd.

I would say that I would like to have some one make a motion to have a committee appointed to make experiments by those who understand and are willing to make the experiments, and find out what kind of apparatus is used. The apparatus which I used I brought from Paris and find it very satisfactory. And I used it for some time, but I have discarded it on account of its causing so much pain. Since I have been using the rheostat I find it better.

I would want a committee to make experiments and get some standard in order to give the instrument makers, and then we want the same class used on the skin as in gynecological work, where we use the high polarity method; we want to know what we want, and the only way to decide it is by clinical experience, and in the absence of any probability of our getting a meter we can get some experience from clinical work. We want to know which coil has a sedative effect and which not. We can then discard the bad and keep the good.

It is a question to me whether we can register the faradic current with a meter. Will we register the voltage or shall we register the volume or amperage? What do you want to register? Must you have a voltmeter?

If a committee be appointed to test these points, coöperation with instrument makers who understand their mechanism better than we do, would be of great value. And as the President has kindly invited me to name a committee including myself, I will mention Drs. Morton, Hutchinson and Massey.

Dr. Morton: I think the electricians will get a standard cell as soon as possible. As for measuring the current, I think they will do that as soon as they know how. As to making the tests, I want to know what the committee is to do?

Dr. Goelett: My idea is if we all work with

the same coils and in the same direction, and if we work with the same ideas, the question would be as I spoke in our clinical work, to test these coils, whether in a private or dispensary practice we agree to a certain form of apparatus for testing and test it in our clinical work.

Motion carried as made.

Dr. L. A. W. Alleman, of Brooklyn, N. Y., read a paper on

THE TREATMENT OF CORNEAL OPACITIES BY GALVANISM.

The employment of the electric current in the treatment of diseases of the eye is not new. Yet our knowledge of the manner in which this agent accomplishes its object, of the indications for its employment, and of the results which may be reasonably expected, is much short of that full and accurate comprehension so much to be desired in the employment of therapeutic agents.

I have endeavored to test thoroughly the efficiency of galvanism, in one class of cases, *i. e.*, opacities, and I invite your attention to a report of my investigations.

After the subsidence of the corneal inflammation which has given rise to the opacity, the eye usually remains for some time in an irritable condition; it flushes easily, and shows evidence of a high vascularity, an increase of nutritive activity in the neighborhood of the scar. Sometimes, vessels are seen running on to the cloudy area; and when this is the case, the prognosis is relatively more favorable.

For some little time the reparative process may go on with much activity, especially in young subjects, the cloud diminishes in density and extent, but more or less quickly, it returns to a condition of normal nutrition; the scar tissue becomes more resistant and the clearing up proceeds more and more slowly, till it finally ceases. In this stage we can often accomplish much by treatment. Such agents as an ointment of the yellow oxide of mercury; calomel dusted into the eye; massage and the like, prolong the reparative process. Sometimes such a radical disturbance as a corneal incision made in performing an iridectomy will favorably influence a case, which has for a long time showed no improvement.

But we finally arrive at a stage where the eye is perfectly quiet and no further absorption of the opaque tissue can be induced.

It occurred to me that in this stage the galvanic current was indicated.

It was a well known fact that it would act as a powerful modifier of nutrition in other parts of the body; why could it not be made to do the same in the cornea?

I believe the reason it had not been more successful, was that when used through the closed

lids, the necessarily feeble current employed on the eye could not produce at the site of the lesion sufficient stimulation to bring about the desired effect, and to meet this indication I had an electrode (I wish to acknowledge my indebtedness to my friend, Mr. W. E. Gibbs, M.E., for his kindly assistance in designing this electrode, and arranging other electrical appliances) constructed which I could use upon the surface of the cornea. It consists of a silver bar, 12 mm. in length, insulated, except at the ends, by a hard rubber shell; the exposed surface at the lower extremity is slightly concave, 7 mm. in diameter. The upper extremity carries a thread which screws into a metal collar, allowing the tips to be changed when necessary. The collar is attached to a copper spring, which still further protects the cornea from injury when the electrode is moved in the fingers, and at the time being perfectly flexible, allows the tip to be adjusted to any desired angle, which greatly assists the convenience of application. The spring is fastened to a hard rubber handle, 10 cm. in length, and 1 cm. in diameter, through which a conducting wire is carried to the binding post, at the upper extremity.

In my first experiments, it was my practice to dip the exposed silver tip of the electrode into a bath of metallic mercury, thereby attaching a globule of mercury to the electrode, which would act as a cushion upon the surface of the cornea; but I have now abandoned this expedient as unnecessary, sufficient moisture being always present, and forming rather a better cushion than the mercury.

A battery of Leclanche cells, a Fleming milliamperè-meter and a rheostat complete my outfit. The rheostat is a modification of one made by Mr. Barrett. I have found this instrument extremely sensitive and satisfactory.

I use for an electrode upon the cheek, a carbon disc with a short metal handle, which fits into a hard rubber shell. The disc is covered with moist absorbent cotton, held in place by the shell, and is renewed each time the instrument is used. I have this electrode made with a very short handle, to be less in the way of the operator. I place this electrode upon the cheek on the same side as the eye to be treated.

I apply the cathode to the cornea. Before placing the electrode upon the face, I direct the patient to touch it to the tip of his tongue, as this gives about the same resistance as through the cornea, and adjust my rheostat till I obtain the current I desire to use. This seems a necessary precaution, as the cocaineized cornea might be seriously damaged, without any sensation of pain giving warning.

The eye being previously well cocaineized, I stand behind the patient, whose head is thrown back, and holding the lids well apart with the

thumb and first finger of the left hand, bring the electrode in gentle contact with the cornea.

As a rule, the applications are of three minutes' duration. I usually begin with $\frac{1}{2}$ milliampère from one to two minutes, and gradually increase the strength of the current, and length of the sitting, till 1 to $1\frac{1}{2}$ ma. for three minutes is reached, if the current is well borne.

I have used as strong a current as 3 ma., but the stronger current seems to be no more efficacious, and is very apt to be followed by annoying irritation.

It is desirable to produce with each application just sufficient stimulation to give rise to an increased nutritive activity, and not to overstep the line, and produce destruction of tissue, paralysis of function, and stasis. The condition of a recent scar is reproduced, the conjunctiva becomes injected up to the cornea margin, and fine vessels all seem, during the treatment, running to the scar. This disturbance subsides by the second day, when the treatment is repeated. If the eye becomes irritable, the applications have to be suspended for a time.

The results of this method of treatment are satisfactory in the extreme. The duration of the opacity seems to make little difference in the prognosis. Occasionally an eye is met with which, for no apparent reason, does not bear the current well, and the very mildest treatment is followed by a severe reaction; such cases are rare. The visual results obtained will depend largely upon the position of the cloud. When concentric with the pupil, little improvement is seen till late in the treatment, but when the pupil is covered by the lap of the opacity, the visual improvement is very marked at the outset; this is due to the fact that the scar always clears up from the periphery towards the more dense centre. When the scar vascularizes easily the prognosis is most favorable, however old or dense the opacity may be.

In the small, very white scars sometimes seen in adherent leucomata, it takes a very long time to influence the centre of the opacity, and the patient, who is elated by the marked visual improvement obtained by the first few treatments, becomes discouraged with the much slower progress of the central opacity, but in such cases as have persevered for some time there has been a slow but steady improvement, even in the dense white scars.

I will cite a typical case from a series previously reported:

Case.—Patient, M. F., presented himself at my clinic in the L. I. C. H. Dispensary, May 14, 1889, giving the following history:

Twenty-seven years previously, had lost left eye from an injury. Two months ago, right eye became inflamed and painful. He had evidently suffered at that time from a severe uauitis, which

had teft a leucoma covering nearly the entire pupillary area. V. $\frac{6}{200}$, not improved by glasses. He was given 1 ma. for one minute at the beginning, gradually increased to three minutes. June 8, after eight treatments, V. had improved up to $\frac{16}{200}$. After some more applications, the current being somewhat increased, 2 ma. for two minutes having been given, vision rose to $\frac{20}{200}$. The eye, which had been somewhat irritable, now became quite severely inflamed, and treatment had to be suspended. The eye had become quiet by August 5, when V. had improved to $\frac{10}{200}$, and by August 27, V. $\frac{20}{200}$ was obtained. Wishing to determine whether or not the treatment was entirely responsible for the improvement, I suspended treatment from this time till October 20, when I found V. $\frac{20}{200}$ as before. Treatment was not again undertaken till February.

After six more applications V. $\frac{20}{200}$ was obtained on March 7, and after eleven more applications, V. $\frac{20}{400}$. The patient received in all three op. average about $1\frac{1}{4}$ ma. for three minutes, and was improved when under treatment from $\frac{6}{200}$ to $\frac{20}{400}$.

Dr. Walling: I have had some experience in treating corneal opacities, and have had most excellent results from the use of the negative current by direct application.

One case I recall to my mind especially, that of a physician who came to me with opacities of the cornea, interfering very much with his vision of one eye. I have no record of the number of treatments. It rapidly cleared up, and his vision is good. He had been treated by some one who had used the positive current, which had lighted up an old inflammatory condition and made it worse. That would seem to be somewhat peculiar. Where there is an inflammatory condition existing, I make application of the positive pole to the outside of the lid, mild in character— $\frac{1}{2}$ to 1 milliampère where it is a chronic condition, then I make application with the negative.

Dr. Massey: I would like to add to my question during the reading of the paper as to what pole the doctor used, that I think the use of the negative pole was wise. To morrow there will be a discussion on the subject of the transference of metals and other substances into the body by means of the electric current, and in dealing with so delicate a part of the body as the eye, we should remember that the positive pole is disintegrated by the current, and that metallic irritation may result. The doctor's experiments and results are very striking, and will be received by the electro-therapeutic world, and I hope by the ophthalmological world, as an epoch making work in the treatment of opacities of the cornea.

Dr. Alleman: I am now continuing my experiments in place of ophthalmic surgery, and with remarkable results, and I feel that there is a field for electric work in my department.

(To be continued.)

Southern Surgical and Gynecological Association.

Fourth Annual Meeting, held in Richmond, Va., November 10, 11 and 12, 1891.

(Concluded from page 853.)

Dr. Cornelius Kollock, of Cheraw, S. C., read a paper entitled

OVARIAN CYSTS, WITH THE REPORT OF A CASE OF OVARIOTOMY IN A YOUNG GIRL.

He said that the causes of ovarian cyst seemed to be still a question *sub judice* in the minds of those who are most progressive, and who have made the greatest advancement in the science of gynecology. Various theories have been put forth by those of larger experience, who are earnest seekers after truth, and who are patient investigators of all unnatural and morbid phenomena. But no satisfactory decision has been obtained from all the patient and searching investigations that have been made as to the cause of this singular, unaccountable, and sometimes fatal neoplasm, characterized by histological diversity from the viscus of which it is a production. Some of the theories seemed, at a glance, to be plausible, but, upon close study, we find they will not bear inspection.

Case.—Miss C. L. H., aged 11 years, 8 months and 19 days; general health perfect in every particular. Menstruation first appeared about two months before she was 11 years of age, and continued with perfect regularity, never excessive or scant, nor was it accompanied by the slightest pain. Her physique was fine in every way. Though less than 12 years of age, she weighed 135 pounds; was strong and active. Her breasts were as full and large as those of a woman at 35. She was very handsome, had a fine voice, and sang beautifully. She was very intellectual, and stood at the head in all her classes in a large high school. I saw her for the first time on the 9th of January, 1891. The abdomen was greatly distended, but facies ovariana was not very pronounced. I was confident she had an ovarian cyst, and I rather suspected she had two. On the 16th of January I made a section about three inches below the umbilicus, and removed a cyst from each side, the one on the left weighing 12 pounds, and that on the right 7 pounds. A more prompt and complete recovery the writer had never seen from the simplest operation. Union by first intention took place, and the sutures, silver wire, were removed at the end of the seventh day. In twelve days she was up and about her room, and on the twenty-third day after the operation returned to her home, a distance of 200 miles.

It is now ten months since double ovariectomy was done on this young girl, and there has not been the slightest discharge from her of any

kind. At each menstrual period there is considerable commotion in the pelvic region, attended with some uneasiness in the head and back; but at each period these symptoms decreased, and the last two were accompanied by no pain whatever. The remarkable physical development in this case still continues. It is now ten months since the operation. She has regained six pounds in weight, weighs 141 pounds, and looks better than before she underwent ovariectomy. This young girl came from the purest and healthiest stock of people in this region. Not an individual on either side was ever known to have any constitutional trouble of any kind. Her mother and family physician, both highly intelligent, say they never knew her to be the least indisposed in any way.

NOVEMBER 11, SECOND DAY — MORNING SESSION.

The Association was called to order by the President at 10 A.M.

Prayer was offered by the Rev. Dr. Newton.

Dr. Thomas J. Moore, of Richmond, delivered an eloquent

ADDRESS OF WELCOME.

Dr. William Warren Potter, of Buffalo, N. Y., read a paper entitled

A MEDICO-LEGAL ASPECT TO PELVIC INFLAMMATION,

in which he said that pelvic inflammations in women have been described, discussed and debated from almost every point of view imaginable, until our medical literature is flooded with articles on the subject, and medical society transactions are teeming and bristling with papers pertaining thereto. So far, however, he had not observed that any one had undertaken to discuss these intra-pelvic conditions from a medico legal standpoint. It was his purpose to discuss that aspect of the question, taking for his text a case that developed an interesting problem in that respect.

After giving a history of the case, Dr. Potter emphasized the following points:

1. The intimate anatomical relations between the pelvic organs and the larger joints of the lower extremities, especially the hip and knee-joints, render them liable to reflexes.
2. The importance of careful diagnosis at the outset, lest grave errors, and possible disastrous consequences, may result from treatment.
3. The medico-legal bearing that errors of judgment in diagnosis and treatment may have in relation to the patient, as well as upon the reputation of the physician.

THE MEDICO-LEGAL ASPECT OF INTESTINAL SURGERY.

Dr. John D. S. Davis, of Birmingham, Ala., read a paper on this subject. He said many

physicians and surgeons, who condemn all mechanical aids for intestinal repair, know not how to use them, never saw them used; refuse to indorse a resection for gunshot or stab wounds, have been known to go in the witness-box for purposes of condemnation and disapproval, when they knew no more about intestinal surgery than a wild Indian about school teaching.

In these days of specialties in medicine, but few general surgeons have either the appreciation, opportunity or disposition to qualify themselves as expert operators in intestinal surgery, but many—to the discredit of the profession, voluntarily appear in the criminal courts of the country pretending to be such—wise and proficient. One of the greatest professional sins of the day is perverted knowledge of conceited ignorance. It is too often that physicians and surgeons weaken and invalidate their opinions to a greater or less degree, by unscrupulous interest in behalf of those employing them, a fact cunningly turned to advantage for defendants in criminal prosecution, and for like reason may become dangerous to the operators they oppose and envy.

To be able to do a laparotomy for stab or gunshot wounds of the intestines, inflicted with murderous intent, and be able to evade civil and criminal liability, the operator must, 1, be able to show evidence of ordinary surgical knowledge in the requirement of the special operation to be performed; 2, he must possess ordinary surgical ability for doing the special operation to be performed; 3, he must exercise ordinary prudence in performing the special operation to be done, as to time, place, antisepsis, asepsis, assistance, nurses, and after-treatment; 4, he must perform the special operation in an ordinarily skilful manner. Hence, to prevent confusion, it will be good, if possible, to determine what constitutes ordinary surgical knowledge, ability, prudence and skill. Upon these depend the whole medico-legal status of the intestinal surgeon, and upon which the expert should be required to depend also. According to the practices and rulings of courts in this country, the word *ordinary*, in its surgical adjectiveness, means that the surgeon shall be capable of and exercise that surgical knowledge, ability, prudence and skill with which a fair proportion of the surgeons of his given locality are endowed, and not that of the highest lights of his profession.

Dr. John A. Wyeth, of New York City, made some remarks on *Ether Anæsthesia*.

Dr. Howard A. Kelly, of Baltimore, Md., followed with a paper entitled *Hand Disinfection*.

Dr. I. S. Stone, of Washington, D. C., read a paper on

THE PEDICLE IN HYSTERECTOMY.

The three principal methods were described

and illustrated by colored drawings, showing the arrangement of the pedicle in the abdominal wound. The author claims a revival of interest in the operation, and that there is need for its frequent performance. The statistics are far better now than ovariectomy claimed after it had become an operation of election, and was firmly planted in public favor.

Particular attention is given by the author to tying off the broad ligaments, and the use of the elastic ligature. Sewing the parietal peritoneum to that of the pedicle, in the extra-peritoneal cases, was also dwelt upon.

The method by ventro fixation has given good results in the author's hands, and serves to accomplish two important purposes, viz.: a speedy convalescence, and avoids the disagreeable sloughing which follows the use of the wire clamp. It may also be used in some cases of short pedicle, where the wire may not easily be applied. The methods were compared and statistics furnished, showing that the extra peritoneal method with wire and pin gave better results than either of the others. That ventro fixation came next, and the intra peritoneal method last, with a large mortality. A method of closing the capsule over the stump was described, which the author claimed would answer for either *dropping* it, or sewing in the wound—ventro fixation. In the latter case, the suspensory sutures are placed and the pedicle sewed in and under the lower end of the abdominal incision. Great care is required in closing the capsule over the raw surfaces of the stump, so that separation may not occur. Owing to the peculiar contractile nature of the capsule, care must be taken to leave sufficient length for approximation of peritoneal surface.

The uterine arteries are to be tied in any case when hæmorrhage is likely to occur, and drainage may be required. Besides reference to methods, the author described the process through which the wound passes subsequent to supra-vaginal hysterectomy.

All myomatous tissue should be removed, which can only be effected, in some cases, by a process of reduction of the pedicle. This is very important, as in the operations where a large amount of myoma is left, more time is required for atrophy and absorption to reduce the pedicle to its proper size. Great danger to the patient is apt to follow, where a broad base of the tumor is left, in either method of treatment, because this mass must be disposed of before the patient entirely recovers.

The author had observed a sufficient number of cases to declare that permanent fixation of the stump to the abdominal wall was the rule, where the extra-abdominal methods were used, and especially when the broad ligaments were cut away to prevent traction.

SECOND DAY—AFTERNOON SESSION.

The Association was called to order by the First Vice President, Dr. McFadden Gaston, of Atlanta, Ga.

The first thing in order was the ANNUAL ADDRESS of the President, by Dr. L. S. McMurtry, of Louisville, Ky. Dr. McMurtry selected for his subject

A PLEA FOR PROGRESSIVE SURGERY.

He said within fifteen years the entire practice of surgery has been revolutionized. New methods have been introduced and new regions invaded; comparatively recent teachings have become obsolete in practice, and modern treatises recast. The science and art of gynecology, which a few years since was limited to a small and narrow field, has grown into a great branch of medical science and practice. Formerly divided between midwifery and surgery, as a minor branch of one or both, gynecology has become an independent and essential department of the healing art.

When Marion Sims announced through the columns of the *British Medical Journal* that he believed the proper course of treatment in every case of gunshot wound of the abdomen is to open the stomach, search for the bleeding points and secure them, and suture intestinal perforations, he was pronounced by many eminent surgeons to be a dreamer. The suggestion of Sims was most timely, and shortly afterwards Bull successfully executed the operation. For years the treatment of opium in full doses has been pursued, with death in waiting. Now there is scarcely a State in the Union that one or more patients have not been rescued from certain death by prompt resort to operative treatment. He mentioned these circumstances to illustrate and emphasize the point, that surgery is advanced more by the aggressiveness of the surgeon than by timidity. In the face of desperate conditions of disease and injury, where there can be no safety whatever in delay and palliation, the only treatment worthy of consideration is the aggressive course which promises success. Under such conditions the most heroic surgery is conservative, and any other course is not conservative.

Dr. Thomas Addis Emmet, of New York, read a paper entitled

INJURIES TO THE PELVIC FLOOR AND THE METHOD OF REPAIRING THE SAME.

Dr. Joseph Taber Johnson, of Washington, D. C., followed with a paper on

THE GROWTH OF FIBROID TUMORS OF THE UTERUS AFTER THE MENOPAUSE.

He said the object of the paper was to put on record cases and opinions in opposition to this view of this important subject, and to aid in re-

casting our views and in modifying our practice.

He had within the past five years seen at least a dozen women with large growing and troublesome fibroid tumors of the uterus, who were over fifty years of age; some of them over sixty. These women had been assured by their physicians that if they could get along somehow, until after the change of life, their tumors would not only stop growing, but that they would lessen in size, and probably go away altogether; at least, the troublesome and dangerous symptoms would disappear. They had been advised against any radical operation, and encouraged to believe that as they grew older, they would get entirely well. In perhaps the majority of cases this might prove to be very good advice; but the point which the author wishes to make is, that as we are now better acquainted with history and behavior of these tumors, that this is no longer safe advice to give. We cannot assure any woman that her tumor may not prove to be one of the exceptional cases, and that it may not grow more rapidly even after the menopause than it did before, or that it may not present complications equally distressing or disastrous. When from forty to fifty per cent. of women subjected to supra-vaginal hysterectomy died from the effects of the operation, this was very safe and conservative counsel to follow. The possible dangers of the tumor were not equal to the probable dangers of the operation.

The author drew the following conclusions:

1. That the "rule" stated in the text-books, that uterine fibromata cease to grow after the menopause, has many more exceptions than is generally supposed.
2. That *when* they continue to grow after the menopause, they pursue a more disastrous course than before.
3. They more frequently become cystic, calcareous, or have abscesses develop in them.
4. These conditions, requiring operation according to well known rules of surgery, the patients are in a less favorable condition for recovery than before the menopause.
5. If the above conclusions are admitted to be true, it must follow that they furnish additional indications for more frequent and earlier resort to the radical operation.

In the hands of the best operators in cases where a pedicle can be secured, the mortality of supra-vaginal hysterectomy is rapidly approaching that of ovariectomy.

THE SURGICAL TREATMENT OF ANTERIOR DISPLACEMENTS OF THE UTERUS.

Dr. C. A. L. Reed, of Cincinnati, Ohio, read a paper on this subject.

He said anterior displacements of the uterus, when they exist to the pathological degree, are the opprobria of the gynecic art. It is indeed

true that many wombs lean far forward without inducing symptoms, but it is likewise true that many of them that are thus malposed do entail symptoms, objective and subjective, that frequently baffle our resources. It is a misfortune too, that many of all the displacements to which the womb is liable, those in which the organ deviates anteriorly to the normal axis are vastly the more prevalent. Thus in an aggregate of four hundred and ninety-four cases by Nonat, Meadows, Scanzoni, Val-leix and Hewitt, quoted by Thomas and Mundè, there were two hundred and ninety-four ante-flexions, and one hundred and eighty retroflexions; while Mundè himself reports two hundred and ninety-four ante-flexions, thirty-three retroflexions and ten latero-flexions in a total of three hundred and thirty-seven cases. As the latter authority is disposed to look upon ante-flexions in minor stages as a physiological (even congenital) condition, it is legitimate to infer that his statistics are based upon observations of displacements in the pathological degree. The conclusion is forced upon us, then, that of all the displacements of the uterus, those of the anterior variety are the more frequent; while the records of practice will force us, likewise, to the conclusion that of all the womb displacements those of the anterior variety are less amenable to treatment than are any of the others.

In the treatment the term *surgical* is employed in contradistinction to any method of treatment by pessaries, tamponnade, or electricity. It may be premised that all surgical methods devised for the relief of these conditions should be directed first, to the removal, when practicable, of the causes of the diseased conditions proper, and, finally, to the readjustment of the diseased organs to the normal physical forces of the pelvis.

In conclusion the author desired the Association to consider:

1. The etiological relationship of contracture of the utero-sacral ligaments to ante-flexion.
2. The possibility of overcoming this condition by such conservative measures as rest, pelvic depletion and appropriate manipulations.
3. The feasibility of removing the obstructive dysmenorrhœa and the sterility usually incident to these cases by the plastic operation which he had described.
4. The inexpediency of forcible dilatation for the relief of these cases and its inability to effect a permanent cure.

THE PART THE SHOULDERS PLAY IN PRODUCING LACERATION OF THE PERINEUM, WITH SUGGESTIONS FOR ITS PREVENTION.

This was the title of a paper read by Dr. W. D. Haggard, of Nashville, Tenn., in which he made the following suggestions:

1. The patient should occupy the left lateral

decubitus, at least during the second stage of labor.

2. Overcome rigidity of the vulvar outlet by the judicious use of chloroform.

3. The presenting part of the child should be supported and not the perineum during the passage of the head and shoulders.

4. Support the head by pressing it well up under the symphysis pubis, by placing the right thumb in the rectum and fingers of the right hand expanded over the occiput.

5. To retard the exit of the shoulders, pressure should be applied to the trunk and shoulder by placing the index and middle fingers of the left hand in the rectum, with the thumb in the vagina to restrain its exit.

6. Support the head and neck by pressure well over the symphysis pubis.

BOOK REVIEWS.

HISTORY OF CIRCUMCISION FROM THE EARLIEST TIMES TO THE PRESENT, with a History of Eunuchism, Hermaphroditism, and the different Operations Practiced on the Prepuce. By P. C. REMONDINO, M.D. Cloth, small 8vo. pp. 346. Philadelphia: F. A. Davis. 1891.

This little book is one that will be welcome not only to the table of the general practitioner on account of its intrinsic worth, but to the medical historiographer on account of the great accumulation of historical facts the author presents, and to the literary class on account of the pleasant style pervading the book throughout. The chapters are as follows: 1. Antiquity of Circumcision. 2. Theories as to the origin of Circumcision. 3. Spread of Circumcision. 4. Circumcision among Savage Tribes. 5. Infibulation, Muzzling, and other curious Practices. 6. Attempts to abolish Circumcision. 7. Miracles and the Holy Prepuce. 8. History of Emasculation, Castration and Eunuchism. 9. Philosophical considerations relating to Eunuchism and Medicine. 10. Hermaphroditism and Hypospadias. 11. Religio Medici. 12. Hebraic Circumcision. 13. Mezizah, the fourth or objectionable act of Suction. 14. What are the benefits of Circumcision? 15. Predisposition to and Exemption and Immunity from Disease. 16. The Prepuce, Syphilis and Phthisis. 17. Some Reasons for being Circumcised. 18. The Prepuce as an Outlaw, and its effects on the Glans.

The six remaining chapters discuss the relations of the prepuce to phimosis, cancer, gangrene of penis, calculi, reflex neuroses and dysuria, enuresis and retention.

Our author makes out a very strong *ex parte* case against the prepuce, and whether accepting his conclusions or rejecting them, one can but admire the author's ingenious presentation of his case.

COMPARATIVE ANATOMY OF THE DOMESTICATED ANIMALS. By A. CHANVEAU, M.D., LL.D. Translated and edited by GEO. FLEMING, C.B., LL.D. Second English edition. New York: D. Appleton & Co.

For the medical man who is so practical that he ab-

jures all literature that is not an every day necessity, Chauveau's work has no charm. The student of natural history and of biology, however, finds this work a most valuable addition to his library. To the teacher of anatomy it is,—or should be—indispensable. Very few works on human anatomy are so beautifully illustrated and pleasantly written as is this treatise on comparative anatomy. The generalization of the various topics are excellent, and the specialized descriptions of the various structures are well worthy of imitation by compilers of anatomies of the human subject. That Chauveau's work is the best for students of veterinary medicine goes without the saying. Indeed there is practically no competition in this field, Chauveau being generally accepted as filling the want completely.

BACTERIA AND THEIR PRODUCTS. By G. SIMS WOODHEAD, M.D. (Edin.), Director of the Laboratories of the Conjoint Board of the Royal Colleges of Physicians (Lond.) and Surgeons (Eng.), etc. New York: Scribner and Welford, 1891. 12 mo, pp. 459. Price \$1.25.

This book has been upon our study table for some two months, during which time we have had frequent occasion to refer to it, and always with satisfaction. The ground covered by the work includes a history of microorganisms; fermentation; the bacteria of certain special diseases, cholera, typhoid fever, tuberculosis, leprosy, anthrax, tetanus, diphtheria, etc.; vaccination; bacteria in air, earth, and water. A single chapter is devoted to the chemical products of bacteria. The book treats of philosophical and applied bacteriology, rather than technique, and cannot fail to prove useful to the practitioner.

THE URINE, THE COMMON POISONS, AND THE MILK. Memoranda, chemical and microscopical for Laboratory use. By J. W. HOLLAND, M.D., Professor of Medical Chemistry and Toxicology, Jefferson Medical College of Philadelphia. Illustrated. Fourth edition, revised and enlarged. Philadelphia: P. Blakiston, Son & Co., 1891.

This well known text-book, as its title indicates, is intended for laboratory use. Teachers engaged in the difficult task of teaching chemistry to medical students, would do well to carefully examine this book, with reference to its use with their own classes.

ORIGIN, PURPOSE, AND DESTINY OF MAN, OR PHILOSOPHY OF THE THREE ETHERS. By WM. THORNTON. Boston: Published by the Author, 1891.

As an example of the author's philosophy, the following may be given. After reciting a long list of articles of the materia medica, which are not found in the body, and which include such substances as opium, mercury, arsenic, colchicum, digitalis, iodoform, and nux vomica, he says: "If such materials as the above list contains are never found in the body, they should never be used in the different forms of sickness for which they are now prescribed." This occurs in the chapter entitled "How to make Medicine a Science." The book is worthless.

PHYSICAL DIAGNOSIS. By JAMES TYSON, M.D.

This is a convenient manual that is well worthy of a place in every student's library. It is concise, yet suffi-

ciently elaborate for all ordinary purposes, and pertains only to diseases of the chest.

THE MEDICAL NEWS VISITING LIST FOR 1892.

Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year), and Perpetual (undated, for 60 patients weekly per year). The first three styles contain 32 pages of data and 176 pages of blanks. The 60 Patient Perpetual consists of 256 pages of blanks. Each style in one wallet-shaped book, pocket, pencil, rubber, and catheter scale, etc. Seal grain leather, \$1.25. Philadelphia: Lea Brothers & Co. 1891.

THE CHICAGO EXHIBITION.—The energetic manner with which the preparations for the Chicago Universal Exhibition have been pushed forward, not only in America, but in England and other countries, gives promise of great success. We are glad to note that an English Royal Commission has been appointed, and that its representatives (Mr. James Dredge and Sir Henry Trueman Wood) have been over to Chicago and satisfactorily concluded all necessary arrangements for the participation of the English exhibitors. From the medical and sanitary point of view the exhibition will certainly prove of great interest. In the first place, the organizers are particularly anxious it should be thoroughly understood that the exhibition is not merely a commercial undertaking. On the contrary, every endeavour will be made to bring together collections of a purely scientific character. There will also be a great number of international scientific congresses, which will commence in May and continue till November. A large building destined ultimately to become an art museum, is to be erected on the lake front. In the meanwhile, the exhibition executive have offered to pay part of the cost for its erection, so that they may use it during the exhibition as a meeting place for congresses. It is anticipated that the congresses will attract so many people that provision has been made for overflow meetings. The auditorium theatre will be reserved for such emergencies, and it is large enough to hold 10,000 persons. The gathering together of so large a number of people will of itself involve many important administrative and sanitary problems. There will be at the exhibition practical experiments and tests of drainage and of the disposal of sewage. The water mains are now being laid down, and these will supply daily from forty to fifty million gallons of water available for drainage, fires, etc. But, apart from this, pipes are being laid, some of them for a distance of ninety miles, to bring pure mineral spring waters to the exhibition for drinking purposes. In looking over the list of the 172 groups into which the objects to be exhibited are classified, many among them will be found of direct interest to the medical profession. Indirectly, America, as the granary of the world, has much to show affecting food supply. It is to America that we are mainly indebted for the cheapness of food in England, and on this cheapness public health in a measure depends. All that concerns the storing, tinning, preserving and transporting of meat, fish, and corn from America is of great practical importance, and never will there be probably a better opportunity of studying these problems than that which the Chicago Exhibition is certain to afford.—*London Lancet*.

AT THE last meeting of the Board of Directors of the New York Post Graduate Medical School and Hospital, J. West Roosevelt, M.D., was unanimously elected Professor of Clinical Medicine.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, DECEMBER 5, 1891.

THE RESPONSIBILITY OF MEDICAL TEACHERS
AND WRITERS.

A caustic article from the pen of Dr. W. H. LINK, of Petersburg, Ind., in a recent number of the *American Gynecological Journal*, calls attention to what he considers some of the abuses in medical teaching. He is particularly incensed at the promotion to professorial positions of men whose principal merit lies in the possession of money, or medico-political influence, or because they have written a book.

Perhaps no one can so fully appreciate the difficulties of a teacher's position as a teacher himself, but the effects of his teaching, as felt by the taught, may also with propriety be brought to his attention. It is certain that many men are willing to make oral statements before a class of undergraduates, which they would not be willing to publish and have subjected to the more unbiased and discerning criticism of their fellow practitioners. Particularly do some gentlemen teach diagnosis much more dogmatically and with show of certainty in the lecture room, than they would care to exercise it at the bedside. The difficulties of practice as met by the young practitioner, are so different from what in many instances he has been led to expect, that a revulsion of feeling toward his teacher, very frequently unjust, and loss of confidence in him takes place, which is not

to be wondered at. This puts upon the teacher the responsibility of giving to his students the best which the profession as a whole has accepted, the latest which the energy of investigators has produced, together with such comments as his individual experience may dictate, but let it be understood that such comments are personal, and not, therefore, authoritative. Brilliancy should give place to the real. These students are soon to put into serious use the lessons taught them, and without the balancing guide which experience alone can give.

More to be dreaded than the careless teacher, is the reckless writer. In these days of numerous medical journals, many of them crying for matter, many essays are printed which do but small credit to their authors. The dangerous papers, however, are those which are written by clever men and good writers, principally for advertising purposes, and which appear in some of the best journals. Papers which are intended principally to show the ease with which the writer can perform a certain operation, and which represent as free from danger some questionable procedure, often fail of their original object, but do succeed in making unqualified men undertake work which they had far better have left alone. The honest practitioner, looking for assistance in his work, and misled by the reputation and official standing of the writer, takes his implied advice and does damage. Ultra conservative suggestions from men prominent in the profession may also lead to baneful results.

A greater responsibility lies upon the writers of books, because of the greater weight usually attributed to them. So long however, as the writing of a book shall be regarded as the best indorsement for a professional position, or for high standing in the profession, so long shall we find books, thrown together from materials found in a convenient library, novel perhaps as to style and arrangement, but representing the opinions of others rather than the knowledge of the author; devoid of originality. Incalculable is the damage done by such books among conscientious workers who look to writers for assistance in times of trouble. It is not always, perhaps we might say, it is not often the book which contains the greatest number of references which is the most valuable. Mere erudition without the leaven of originality and experience, is heavy

and valueless. As a type of a most excellent book, we would mention BRINTON, *On Diseases of the Stomach*. This work is replete with facts, carefully determined individually by the author; is a veritable mine of information, and may be accepted as a model monograph.

Perfection in books is not to be expected, nor agreement in opinion with everybody, but books which are made to sell, or books which are written with some other reason than to instruct, can usually be detected, and should be plainly stamped for what they are worth. This throws some responsibility upon reviewers. Every book accepted for review, is entitled to a sufficient study to determine its value. In many cases this can be done easily and quickly. Reviews should be considered as made not so much for the benefit of authors and publishers as for the guidance of buyers. Indiscriminate praising of all books reacts against meritorious works, and assists in the sale of many books which should fall flat. From a perusal of many book notices it would seem that many reviewers believe that an extract from a book's preface is the best possible review of it.

The practice is to be denounced of condemning a book on such minor grounds as grammatical errors, or statements so gross as to be evident slips of the pen, and unlikely to mislead any one, while at the same time failing to call attention to its valuable parts. But the duty of the reviewer is plain, to stamp as spurious all books which bear the marks of having been written for personal ends only.

Let our teachers and writers feel the responsibilities which rest on them and weigh well their views before giving them to their brethren.

SECTION WORK.

With this issue of *THE JOURNAL* there is a practical completion of the work of publishing the proceedings of the late meeting of the American Medical Association at Washington. The work has been as methodically done as the matter in hand would permit, and being off with the old we are now on with the new.

Already the officers of the several Sections are engaged in securing the right men for special lines in their several departments, and we are informed that their success betokens the next as

the grandest meeting in the entire history of the Association. This sounds very loud to those who were at Cincinnati, Nashville and Washington, but all the same, the winds that whisper the words so softly in our ears, are harbingers whose voices may be relied upon as telling only the truth, the whole truth and nothing but the truth, and if you are inclined to be the least bit skeptical, begin to think of your visit to Detroit next June not only for the purpose of verifying our statement, but to be mentally, physically and professionally refreshed.

At the late meeting in Washington, the Association declared its wish to have a complete stenographic report made of not only the general meetings, but also of each of the Sections, so that there was fair and sufficient warning given that whatever a member gets on his feet and says out loud will be written down. The discussions will all be reported, and the stenographers will, at the close of each day's session, hand over to the Section officers their notes. The Section officers will put them in form for publication, first winnowing the chaff from the wheat, so that there may be a gathering of material that will fairly reflect the progress of our art during the current year.

Three chairmen of Sections inform us that their programs are practically complete, but of course are held open for amendment. We are pleased to make a note of this, because of its indication of an enthusiasm in their work that is highly commendable. These chairmen know just what they are about, in assigning lines of thought for development to the men who are already known for their professional achievements in particular directions.

Furthermore, these same chairmen tell us they are making special efforts at securing the best known men to take leading parts in the discussions. This is for the purpose of bringing out a careful expression of opinion that is pertinent to subjects of which such men are conceded to be masters, or very diligent students.

While we fully appreciate the value of a carefully prepared paper by a good reasoner, it is the commonest thing that happens at a society meeting, for a paper that has not much in it, to develop a discussion of the utmost value. Discussions should be and usually are the life, body and soul of the meetings.

METALLIC BODY EXTRACTED FROM THE VITREOUS BY THE ELECTRO-MAGNET.

In the September number of the *Australian Medical Gazette* DR. BARRETT reports a case in which the electro-magnet was successfully used to remove a chip of iron from the vitreous chamber. The patient, a male aged 21 years, while using a hammer, felt something fly into his eye, penetrating the cornea. When seen by his physician, a day or more afterwards, there was evidence of a corneal wound and the crystalline lens was seen to be swollen and opaque. After a few days had been allowed to pass, and the lens had softened sufficiently to favor its evacuation, an operation for its incision was performed. During this procedure, a wave of vitreous humor passed into the anterior chamber and through the operation wound. The foreign body escaped into the anterior chamber also, and thence it was promptly extracted by the magnet. The patient did well ultimately, his vision being $\frac{6}{18}$ C + 13 D., a result which has not been surpassed in any recent similar case that has passed under our notice.

DOMESTIC CORRESPONDENCE.

Etiology of Scarlet Fever.

Journal of A.M.A.—Dear Sir: In your last issue you say you will take pleasure in publishing communications on cases like the following, and as it will probably be of some value in the etiology of scarlet fever, I will report it. Six weeks ago yesterday Chattie Myers, aged 10 years, went to Morley, a village four miles from this place and was in a room for an hour in which another little girl was suffering with scarlet fever. The little girl had been sick three days. Chattie came home and just two weeks afterwards was taken down with the disease, was quite sick and is now just about through the shedding process; her parents have kept the different portions of skin and have handfuls of it in the shape of fingers, toes, etc., and during this week Chattie is bloated and threatened with a severe attack of uremia. So there is no doubt in my mind that scarlet fever is contagious during the first few days, but it has not proven very contagious (in this locality) as it has not spread at all in this community. There were two cases here last winter and no effort made to keep it from spreading, but it did not do so. It seems to me that in an intensely malarial district scarlet fever, diphtheria and typhoid fever lose their extreme virulence.

At Charleston, a town of 1,500 inhabitants, they have recently had an epidemic of diphtheria, and only one child died, and it was an unhealthy child before it was attacked. Within the last few years there have been sev-

eral cases of scarlet fever in this and Mississippi county, but people are not uneasy when a case is reported. As to treatment and management of either one of the above named diseases, there is rarely anything done in the way of isolation or to prevent neighbors from visiting and sitting up with the sick. So your advice as to quarantine is of no value here. I recollect on one occasion a gentleman from Tennessee came to Charleston and his son was taken down with scarlet fever, and the father allowed his other children to go around and play upon the streets, and the citizens became so incensed that they talked of mobbing him, but later in the season the scare was over and there was no more comment upon a case of scarlet fever than there was of one of intermittent fever. There is some influence that is of benefit to the Swamp Doctor. Either the malaria helps him in his treatment or calomel, quinine and opium are three mighty good remedies in scarlet fever. We hardly ever know what we are treating until half the neighborhood have been exposed, and then if the case is mild, which is generally the case, we call it "scarlet rash," which the laity thinks is not contagious or dangerous. After the patient begins to lose his scarf skin and probably has a convulsion from uremic poisoning, we tell the people that it is genuine scarlet fever and they had better keep the neighbors away.

Respectfully,

Oran, Mo., Nov. 23.

W. P. HOWLE, M.D.

SELECTIONS.

COMPRESSED MEDICINE TO BE USED HEREAFTER IN THE ARMY AND NAVY.—Army and Navy officers, and particularly those of the medical branches, evince great interest in a contract which was awarded at the War Department for a new system of carrying medical and surgical supplies for an army. Ever since the last Sioux campaign, there has been a growing demand for a plan by which supplies needed by the surgeons could be placed in a more compact form than liquid, and carried with greater safety and economy. The result of to day's award is believed to be as near perfection as possible.

In a small, light wooden chest, 23 inches long, 14½ inches wide and 17¾ inches high, are sixty square bottles, containing as many different kinds of medicine, but in compressed tablet form, none of them being larger than an ordinary peppermint lozenge. One of these lozenges or tablets contains all the necessary ingredients of a famous liniment, and when dissolved in an ounce of distilled water its healing properties are the same as if it was in liquid shape and in a big glass jar. Some idea may be formed of the perfection to which the art of compression has been brought, by the fact that if the contents of this small brass-bound chest were liquefied and in their customary jars and bottles, they would occupy nearly one-half of the space of a regular freight car.

There are two of these chests to be supplied to each battalion of 200 men. No. 1 is marked with the Geneva Red Cross and inscribed "Medical Supply Chest," while the only difference in No. 2, so far as outward appearance is concerned, is the inscription, "Surgical Supplies." With certain kinds of medicine, like cough mixture, used in quantities, a bottle holding a gill of the compressed tablets is equivalent to a gallon of liquid, and should the bottle break, the merits of the tablet are not impaired in the least.

Contract was awarded for 200 of these chests, and one of each kind is to be placed under the driver's seat of an ordinary ambulance, or in case of field service and when pack-mules have to be utilized, the chests are suspended on each side of the pannier, their weight with contents being but 85 lbs. each. On the top of each bottle-stopper is the name of its contents, and fixed securely in the lid of each chest is a list of its contents, for the information of the surgeon or hospital steward in charge. Surgeon J. C. Merrill, of the Surgeon-General's office, who has been supervising and conducting the experiments, declares that the new system will revolutionize the mode of supplying needed articles for an army, and will be of value as well to the National Guard organizations of the various States. Iowa is already in the field with inquiries on the subject of these chests, and it is quite likely that at the next annual encampment of the troops of the Hawkeye State, these necessary medical and surgical adjuncts will be seen in abundance.

Whisky, brandy, alcohol and castor oil are carried in liquid form, their ingredients rendering it impossible to form them into tablets, but cod-liver oil is compressed. In making the investigations, the English army system of carrying medical supplies was examined, but while lightness was obtained by means of wicker baskets covered with rawhide, it was demonstrated that if the hide became dampened it would twist in all shapes, and destroy the bottles which the wicker baskets were filled with. Hence a light wooden chest was determined upon, and a New York firm provided what proved to be the best and most attractive-looking model. It was accordingly awarded the contract. — Washington Special to *Chicago Tribune*.

THE PORO-PLASTIC FELT JACKET, FOR SPINAL TROUBLES.—I do not propose to indulge here in a lengthy dissertation upon the etiology and pathology of spondylitis, or Potts' disease, but will present a few facts based upon an actual experience in the surgical and mechanical treatment of that distressing malady, as well as of lateral curvature of the spine.

The advantages of the poro-plastic felt over plaster-of-Paris and other suggested agents as a material for spinal jackets are many. Its most prominent claims for superiority are its *lightness*, its *sporsosity* and its *resisting power*. The weight of a spinal jacket made of this material for an adult is only one-fourth of that of the plaster-of-Paris jacket for the same patient. This is a point strongly in its favor when we remember how delicate are those persons who have to wear such an appliance.

That poro-plastic felt is the most highly porous material yet suggested for a spinal jacket no one who has taken the trouble to investigate the matter will deny. While our most eminent American orthopaedist claims that a plaster-of-Paris jacket is quite porous, I must say that I have failed to discover any porosity in such a jacket when made in accordance with that eminent gentleman's instructions. The amount of air likely to pass through a half dozen consecutive layers of a plaster jacket, with an abundance of extra plaster rubbed thoroughly into every pore or mesh of the cloth employed in its construction, is certainly reduced to a minimum, if there be any at all. The amount of support or resistance in the poro plastic felt can be increased at will by simply multiplying its layers where such support is desired.

The poro-plastic felt adjusts itself to every irregularity of the parts with the greatest precision and nicety, while its elasticity permits free and unimpaired respiration—important points when the comfort of the patient is taken into account.

Before proceeding with a description of the mode of preparing a spinal jacket, I desire to refer briefly to two important points in the diagnosis of Potts' disease—not for the benefit of the orthopaedic specialist, but for the guidance of the general practitioner under whose observation such cases usually first come. The two diseases with which it is most likely to be confounded are lumbago and anæmia, or congestion of the spinal cord. This confusion results in much delay in the beginning of the proper treatment of the trouble.

The prominent diagnostic symptoms in Potts' disease just referred to are pain at a given point along the spinal cord, which is relieved by catching the patient under both arms and lifting him up to a point of complete suspension, and the peculiar gait noticed in the early stages of the disease, when the patient walks with a cat-like tread upon the balls of the feet, and avoids throwing any weight suddenly upon the heels.

The mode of preparing the poro-plastic jacket is simple enough to popularize it with physicians, even in the most remote sections of the country. The first step in the manufacture of a felt jacket is to make an accurately fitting plaster-of-Paris jacket. This is done in the usual manner, the patient is suspended according to Sayre's method, and the jacket is made over a thin, closely-fitting shirt of gauze or other light material. The width of the plaster bandages to be employed must be determined by the size of the patient. If he be an adult, well developed, a three inch bandage should be used; if a child, a two or two and a half inch bandage is the proper width. Of the width chosen, six 5-yard bandages will be required. Only two of these should be placed in the water at a time, the remainder to be put in by an assistant two at a time as the work proceeds. A bandage is ready for use when the water in which it has been submerged ceases to bubble or effervesce. The first circular layer of the bandage should pass around the hips at least two and a half inches below the crest of the ilia, so as to secure a liable basis of support for the superstructure. The lower half of the jacket should be allowed to "set" or harden sufficiently to sustain the upper half, and thus prevent sagging near the center. Always let the jacket extend well up into the axilla. We must rely mainly upon the hips and chest walls for our points of support.

When the entire jacket has hardened sufficiently we divide it in front along the median line from the top downwards with a strong, sharp knife. Instead of guiding the knife with fingers of the left hand, I follow a groove in a piece of zinc previously placed in position under the gauze shirt, corresponding with the median line and extending from the sternum well down on to the pubes. This zinc strip is two inches wide, and has a groove extending through the centre from end to end.

After the jacket (including shirt) is removed, its cut edges should be immediately brought together and held in apposition by a bandage passed repeatedly around it, and then allowed to become thoroughly dry by exposure in the sun or on a stove or range. The plaster jacket thus completed serves as a mould for making a cast of the body. This cast is made by filling the jacket or mould with plaster-of-Paris mixed with water, of the consistency of wheaten dough. A cylinder of wood or metal should be set in the middle of the mould, equidistant from all sides, so as to leave a hollow opening through the finished cast for convenience in handling, etc. Over this cast the felt, previously softened by immersion in hot water, is laid and allowed to harden, care being taken to rub down and smooth out all wrinkles and irregularities. When this has become thoroughly hardened, it is removed from the cast, and then becomes itself a cast for the addition of any extra layers that may be desired for the purpose of increasing its strength at any point necessary. These extra pieces or parts after being properly fitted, are riveted on to the first or main layer of the felt. The corset is now trimmed, the edges are bound with soft leather or sheep

¹ Read at the Meeting of the Mississippi Valley Medical Association, St. Louis, Mo., Oct. 14, 1891, by Ferdinand King, M.D., of New York.

skin, and a row of hook-eyelets put on either edge in front for the laces that secure it firmly in position on the patient. If additional strength is desired on either side of the corset, it may be secured by steel strips placed transversely between the layers of felt and held in position by small rivets. If the spondylitis be located in the cervical portion of the spinal column, thus necessitating the use of the jury-mast, the latter may be riveted on to the upper part of the felt jacket. Likewise a leg splint or brace for hip-joint trouble may be riveted on the lateral lower border. The solidity of the felt assures solid support in either case.

As stated at the outset the poro-plastic felt is exceedingly porous, permitting free ingress and egress of the air as well as the free escape of skin excretions from the body. Even greater ventilation may be secured by inserting shoe-eyelets distributed over the surface of the jacket at such points as may be desired. These eyelets will add to, rather than detract from, the strength of the appliance, thus serving a double purpose.

As a general rule the jacket is fastened in front by ordinary corset lacings, but if the greatest possible space for the expansion of the chest walls is desired, as is usually the case in treating lateral curvature, elastic lacings may be employed.

In conclusion I would urge upon the profession the importance of securing the proper make of felting for the manufacture of spinal jackets, as disappointment will certainly follow the employment of any other than that which I have been using for the past three years. I do not know by whom this felt is manufactured, but I do know that it may be obtained from any reputable instrument dealer in this country at very small expense.—*Int. Journal of Surgery.*

EXTIRPATION OF CARBUNCLE.—Dr. Riedel has practiced immediate extirpation of carbuncles since 1883, and finds that this procedure is far preferable to the customary treatment by deep incisions. The operation is performed as follows: A circular incision is made through the skin around the infiltrated area, and from this a number of vertical incisions are made to radiate toward the healthy peripheral parts. At least four cutaneous flaps are thus formed, which are separated from the infiltrated tissues, and then the latter are dissected off from the fascia of the subjacent muscles. The hæmorrhage, which is frequently profuse, is controlled by means of compression and tampons. On the evening of the day of operation the temperature has usually become normal. On the following day the swollen cutaneous flaps are approximated; the opening in the center provides for drainage. The advantages of this treatment are: 1. A dangerous inflammatory focus is replaced within half an hour by a perfectly harmless loss of substance in the skin and subcutaneous tissue. 2. An extension of the local process or general infection are both excluded. 3. The loss of healthy integument at the periphery of the carbuncle is reduced to a minimum. 4. For this reason healing takes place rapidly and a good cicatrix results.—*Deut. Medicin. Wochenschr.*, No. 27, 1891.

SKIN GRAFTING AFTER EXCISION OF THE MAMMA.—Mr. Watson Cheyne, F.R.C.S., reports two cases illustrating the value of Thiersch's method of skin grafting in closing recent wounds, and thus enabling us to operate in cases where otherwise we might hesitate, as well as to perform the operation more effectually in less severe cases. In excising the breast great care should be taken to remove also all the fascia covering the pectoralis and other muscles exposed in the wound, partly because by doing so lymphatic vessels lying on this fascia, which might become infected, are also removed, and partly in order to lay bare a very vascular surface on which to lay the grafts. The grafts consisted of half the thickness

of the skin, as advised by Thiersch, because the chances of adhesion are greater. The skin having been well purified, long strips, about an inch in breadth, are cut with a long razor, preferably from the thigh, and are spread out on the raw surface, after the bleeding has been completely arrested. The strips must lie closely side by side—in fact, they should rather overlap each other and the edges of the wound. The extent of the wound to be covered at the time of operation will depend on the condition of the patient and the circumstances of the case. In any case it will always be best to cover the whole of the pectoralis at once. If it is not thought advisable to cover the whole of the wound at the time of the operation, any portion left can be readily grafted after the wound is granulating.—*Lancet.*

THE TREATMENT OF APPENDICITIS.—The treatment of appendicitis was recently discussed at a meeting of the Philadelphia County Medical Society, and although nothing new was brought forward, the discussion is of value as an exposition of the views of a number of distinguished physicians and surgeons on this still obscure subject. Dr. Pepper ably defended the medical side of the question, and urged moderation in the operative treatment. "If every case of appendicitis were operated upon," said he, "the mortality would be tenfold what it is now. As a general rule, these cases recover under medical treatment and remain permanently well afterward." He was entirely opposed to surgical measures in the intervals, and claimed that records showed that thorough treatment, hygienic, dietetic and medicinal, has been followed by complete cure. Mr. Bryant, the famous English surgeon, who was present, fully agreed with Dr. Pepper, and sententiously remarked that delay in operating was the wisest course in the majority of cases. He thought that if the disease progressed slowly, commencing with localized pain and tenderness in the right iliac fossa, and attended with only slight swelling, the surgeon's knife could safely be dispensed with. He was opposed to purgation in these cases, and places his reliance upon rest and diet, together with belladonna externally, and opium internally. In all acute cases, however, or where symptoms of peritonitis develop, it was the surgeon's duty to interfere at as early a date as possible. As regards the propriety of operating between the attacks, Mr. Bryant's views were characterized by true conservatism. He called attention to the fact that in the majority of cases there is no second attack, and even if there is, it can be treated on the same lines as the first, operative interference being reserved for cases in which the symptoms do not rapidly recede. Mr. Bryant also prefers, in most cases, an incision more posterior than the right semilunar line, finding it easier in this way to reach the cæcum; and in the event of failure to discover the appendix, he contents himself with irrigating the part and treating it by the open method. Drs. Keen, Baldy and Price emphasized the importance of having a surgeon associated with the case from the beginning, so that he may become familiar with its features, and be ready to deal intelligently and promptly with the conditions when the time for operation arrives. The advisability of administering purgatives was also considered, and to judge from the tenor of the discussion, there exists still much difference of opinion on this point. Some favored the use of calomel and podophyllin, others the salines, while still others were opposed to purgation.

The discussion, of which we have given this brief outline, serves, however, to emphasize the inadequacy of our diagnostic resources, and to this should be attributed the divergence in the views of eminent physicians and surgeons on the question of treatment. If it were possible in most instances to recognize the exact condition present, it would be an easy matter to decide whether any given case is to be subjected to medical or surgical

therapeutics. The presence of pus or perforation calls for immediate surgical intervention, but, as Dr. Baldy justly remarks, "there are a large number of border-line cases in which it is next to impossible to say whether pus is present or not." At any rate, the association of a surgeon with the physician in the management of cases of appendicitis is a step in the right direction, and one calculated to produce a greater degree of unanimity in the views of physicians and surgeons, both as regards diagnosis and treatment.—*Internat. Journal of Surgery*.

THE OCULAR MUSCLES IN THOMSEN'S DISEASE.—Raymond (*Union Méd.*, June 11, 1891) describes two cases of Thomsen's disease. In one the internal recti of both eyes were hypertrophied, and the other eye muscles were becoming so. In certain movements of the head and neck there was coincident spasm of the lids; the reaction of the pupil was normal in both eyes; the optic discs and color sense were also normal. The left eye was astigmatic and slightly myopic, but the right eye was normal. The superior recti were affected with spasm in the second case; the pupils reacted very quickly to light; the optic disc and visual field were normal.

IN DIPHTHERIA, locally, Marchand's peroxide of hydrogen and whisky, internally, have established their value. A word in regard to the use of the peroxide: It should always be purchased in the smaller 4-ounce bottles, protected from the light by blue glass bottles, and corked with rubber. That sold by the druggists from large bottles is, in the majority of cases, worthless. It is a very unstable article, and unless it causes immediately a white, foamy reaction when brought in contact with the false membrane, it should be discarded, and another lot obtained. I am satisfied that I use it more freely and more persistently than most practitioners. I use mops made by twisting a sort of absorbent cotton upon sticks, using as many as thirty or forty in the twenty-four hours. Such mops will take up nearly a half ounce apiece, and, when forced well back into the pharynx, reach all parts. The gagging and resistance of the child assists in the distribution of the fluid. As soon as a mop has been used, it is committed to the fire. In this way I have treated the worst as well as the milder forms of diphtheria with complete success. I believe that the systematic use of definite, although often toxic doses, of whisky, even in children of tender age, are the surest safeguard against heart failure.—*Larabee, Am. Pract. and News*.

THE TREATMENT OF VARICOSE ULCERS.—Dr. J. Hartmann recommends ichthyol in the treatment of varicose ulcers of the leg. After cleansing the sore with soap and warm water he applies pure ichthyol to the ulcerated surfaces and covers them with a thick layer of cotton, which is secured by an unstarched gauze bandage. The application produces an intense burning pain which usually lasts only for a short time. During the following days the patient experiences great relief, but as soon as the sore again gives rise to pain or discomfort, the dressing must be changed. Even at the first change of dressings, the ulcer will be found to present a better appearance, it will look cleaner and, unless very chronic, will show signs of granulation at the margin.—*Correspondence Blatt. f. Schweizer Aerzte*.

THE FORMATION OF A GASTRIC FISTULA IN CANCEROUS STENOSIS OF THE CARDIAC END OF THE STOMACH.—Dr. Lauenstein advises that in cases of marked cancerous stenosis of the cardiac end of the stomach, it is better not to resort to formation of a gastric fistula. He has had two cases of carcinoma of the cardiac, in which access to the stomach was prevented by the tumors

which were situated under the diaphragm. The neoplasms had invaded the mucous membrane of the stomach, which had to a certain extent lost its digestive functions. It may also happen that the stomach is so firmly fixed by adhesion of the tumor at the cardia that the formation of a fistula is attended with great difficulties. For these reasons the author prefers rectal alimentation in this class of cases. A cancer of the cardia should be suspected if the œsophageal bougie encounters resistance at a depth of 38 to 41 centimeters from the teeth. In one of his cases the author noted a loud systolic sound in the epigastrium, synchronously with the pulse, which the autopsy showed was due to pressure of the tumor on the aorta.—*Centratbl. f. Chirurgie*.

IN THE SWISS CANTON of St. Gaul, a law passed in 1890 provides that habitual drunkards may be placed under care in an inebriate asylum, for periods varying from nine to eighteen months, either on the ground of voluntary submission, or by direction of the local authority (District Council). Proceedings may be initiated by a relation or guardian of the drunkard, by any public body, or on the sole responsibility of the council, but they must be justified by a certificate from the medical officer of health, that such seclusion is necessary for the cure of the patient. If his personal property is insufficient to meet the expense, the public funds are to be applied, not only for his own maintenance, but, if necessary, for the support of his family during his enforced absence.—*Journal of Inebriety*.

THE Commissioners of the Lancashire Lunatic Asylums state in their annual report just issued, that "although drunkards are not generally regarded as insane, it is a question whether the habitual tippler might not with advantage be considered an irresponsible being, and treated as such." They point to the fact that in not a few cases the only cause that can be detected for a patient's insanity is the intemperance of one or both parents.—*Ibid*.

INEBRIETY is curable in nearly all cases in the early stages. After repeated poisoning or intoxications for years, conditions of degenerations come on, from which recovery is very rare. The drink impulse may die out, or be permanently checked, but the injury to the brain and nervous system remains.—*Ibid*.

INEBRIETY, as a disease, is more seriously affecting the moral and civil affairs of state than any other that will come under the notice of the practitioner of medicine. Excepting the poison of syphilis there is none other so productive of far-reaching morbid processes and capable of affecting all the tissues of the body as alcohol. The results either of moderate drinking or chronic alcoholism will extend to generations to come and show in crime, drunkenness, or nervous disorders. Inebriety and its attendant maladies are conditions of progressive degeneration. And while one may stand surprised when he starts out to trace up the history of a patient and finds that it can be followed back to a drinking father or mother, yet it is better for the physician and patient, for the former will know what is required of him and the latter will recognize the ability that may alleviate his trouble. But practically there is no limit to the possibilities of convincing information on this subject, and the more it is studied the less is there to be said in favor of the use of alcohol in any form.—*Dr. Reeder in Lancet-Clinic*.

GELSEMIUM is said to be an efficient remedy for toothache; at least, for the non-inflammatory varieties. Fifteen minims of the tincture, with two grains of quinine, are given every hour for three doses if required.

THE INSOMNIA OF CONTINUED FEVERS AND ITS TREATMENT.—In the earlier stages of these fevers insomnia is pretty certain to accompany the hyperthermia, while sleep often attends a fall in the temperature. It would seem that overheated blood is itself inimical to sleep by exciting the cerebrum. Certain it is that cold bathing—the cold or tepid bath—and antipyretics that bring down the fever, quiet the nervous disturbances and promote sleep. Hence, for the restlessness and insomnia of typhus and typhoid fevers, there is often no better treatment than a cold bath of about fifteen minutes' duration, the temperature of the water being from 60° to 75° F., and during the bath cold water may be poured on the head in cases of extreme pyrexia with restlessness and delirium. While fifteen minutes ought to be long enough to depress the febrile heat to nearly the normal, in some cases the bath may be of longer duration.

Where the cold bath is impracticable, from difficulties on the part of the patient or his surroundings, some one of the new antipyretics may be tried. There is much testimony in favor of acetanilid as a nervous sedative in fevers. Five grs. every hour for three or four doses (in an adult), will generally lower the febrile temperature two or three degrees, and one or two hours of quiet sleep (especially if the medicine be given in the night-time) is almost certain to follow. By many practitioners and hospital physicians, analgesin is regarded as the preferable hypnotic; the dose should be double that of acetanilid.

The antipyretics, though they undoubtedly have a marked action on the thermogenic and thermotaxic heat centres, which are under abnormal irritation by the fever poison, an action which is extended to the higher cerebral centres, certainly do not affect the infectious agent, and hence the course of the fever is not influenced by them. Their prolonged use is probably attended by some cardiac depression (an evil to be especially shunned in fevers), and the best clinical authorities are shy of them, seeing no permanent advantage in the continued administration of these medicaments, but possible mischief. At the most, their employment is restricted to the obtention of such sedation as is needed for the nervous disturbances.

In regard to pure hypnotics, chloral is undoubtedly the best one. Sometimes, in the later stages of the fever, 20 drops of deodorized tincture of opium is of service. Sulphonal, chloramid and the newer hypnotics are not of service. Alcohol, in not too large doses, has a place in this line of therapeutics.

Febrile insomnia is essentially a toxic insomnia; this has been made apparent by the investigations of the last few years. Whether it be the microbes or their ptomaines, or both which excite the cerebrum and derange the nervous functions, has not been yet positively determined. Uræmia probably enters as an important factor; in the active stages of fevers, and in the declining stages when the circulation is oppressed and languid, and the prognosis is grave, elimination by the kidneys is always imperfect. Hence an important part of the treatment should be to promote the excretion of the poison and the removal of effete matters. Unfortunately, this indication can be but imperfectly met. All that can be done is by suitable nutrients and stimulants to sustain the organic forces in their struggle with the foe, and to favor elimination by the kidneys and other excretories. The various diluents (lemonade, barley-water, effervescent drinks, plain water, etc.) which are so freely given, because so constantly craved, promote excretion by the kidneys. Milk is often prescribed *ad libitum* as the sole drink and nourishment; its diuretic properties are well known. Some clinical authorities are in the habit of ordering mild diuretic mixtures (solutions of nitrate of potassium, of sweet spirits of nitre, with sometimes the addition for several successive days of a little digitalis) all through the fever, and claim good results.—*Therapeutic Gazette*, September 15, 1891.

TREATMENT OF TYPHOID FEVER.—"Dr. Tordeus has been employing with considerable success a treatment for typhoid fever in the St. Pierre Hospital, Brussels, which consists essentially of moderate doses of an antipyretic combined with an antiseptic. Thus ten grains of acetanilide and an equal quantity of resorcin, or about half that amount of thymic acid, are made up into a five-ounce mixture with a compound decoction of aloes, and tablespoonful doses given every three hours. This was found to exert a remarkably beneficial effect not only on the temperature, but also on the general condition of the patients. From trials made with acetanilide alone, it was evident that the antipyretic effect was almost entirely due to the combination with it of the resorcin or the thymic acid. Several children were included among the patients so treated, the doses given being, of course, proportionately smaller. Dr. Tordeus is of the opinion that treatment of a similar description will be found suitable in other zymotic diseases; indeed, he has tried a combination of acetanilide and benzoic acid in measles and in croupous pneumonia, the latter drug being selected in preference to resorcin on account of its possessing expectorant as well as antiseptic properties."—*Lancet*.

THE DRY TREATMENT OF CHANCEROIDS.—It is generally conceded that if chancroidal ulcers can be kept very dry, a great step has been taken toward their rapid healing. With this view, the following procedure has been used to some extent in the surgical divisions of Bellevue Hospital, New York: A small roll of absorbent cotton about one-half an inch in diameter and long enough to surround the penis just behind the corona, is put in that position after the prepuce has been well retracted. A rubber thread band is slipped over this ring of cotton in order to hold it in place. By this means the sulcus behind the glands is obliterated, which is especially liable to retain the secretions, and the prepuce is held back from contact with the ulcerated surface. The cotton absorbs the exudation from those surfaces almost as soon as formed. The dressing is light, is easily handled, and may be renewed as often as need to keep the parts in a dry condition. In addition to chancroids, herpes preputialis and venereal warts have been found to heal rapidly under the use of this dressing; sometimes no other treatment has been found necessary for these local lesions.—*Canada Record*.

THE PROCLIVITY OF WOMEN TO CANCEROUS DISEASE.—Dr. Snow says that the number of women who apply at the Cancer Hospital is twice as great as that of the men, and this notwithstanding that the cases of cancer of the lip and tongue are almost all males. This excess of females is due to the prevalence of malignant disease of the uterus and mamma. He then asks why these organs are rich in cell-elements. Second, they are frequently exposed to irritation. Third, their normal condition and nutrition are interfered with by circumstances which he considers are more or less directly the result of what is called civilized life. Of these he specially blames constipation, over-pressure at school, the abuse of tea, and tight-lacing.—*Medical Record*.

THE INFLUENCE OF GRAVE-YARDS ON PUBLIC HEALTH.—Dr. J. W. Carhart, of Lampasas, Texas, has written a paper on this subject in which he drew the following conclusions:

From whatever standpoint this subject was approached, it must be with care and gentleness, since the graveyard, though a constant menace to public health, had a pseudo-sacredness fostered by the profoundest sentiment of our nature.

The method of the disposal of the dead should be founded on reason and not on custom or sentiment.

The interment of the dead in the earth was never en-

forced by a statute, Jewish or Christian, and was merely incidental to both dispensations.

No law, human or divine, require us to dispose of the dead in a manner prejudicial to the health and comfort of the living.

While it might be an open question as to the right of the State to decide as to the manner of the disposal of the dead, unless in exceptional cases, it was clearly the province and duty of the State to prevent such disposal as would in any wise jeopardize the interests of the living.

From all the facts at our command, we were led to the conclusion that the graveyard should become a thing of the past, and that incineration was the method most in accordance with science, sanitation, æsthetics, reason, and religion.

He would add, as a corollary to these several conclusions, that, since the intelligent, broad-minded physician was the almost exclusive guardian of public health in seeking to prevent the development and spread of disease, it was plainly his duty, when cemeteries were being located, to use his best endeavors to have them so placed as to jeopardize as little as possible the public health; and for its moral effect he should encourage efforts to beautify existing cemeteries; and that he should seek, as fast as possible, without too much violence to the tender sensibilities of the masses, to encourage incineration of the dead, or some other method more in harmony with sanitary science than the common modes now practiced.—*Medical Age.*

MISCELLANY.

MISSOURI VALLEY MEDICAL SOCIETY.—The Medical Society of the Missouri Valley will be held at Lincoln, Nebraska, December 17 and 18, 1891, at the Lindell hotel, corner Thirteenth and M streets.

First Day.—7:30 P.M.—Registration of Committee of Arrangements. 8:00 (a) Organization. (b) Report. Committee on Credentials. (c) Reading Minutes. (d) Miscellaneous Business. (e) Report. Committee of Arrangements.

Address by the President:—Higher Medical Education in the Missouri Valley.

Presentation of Papers.

1. Tumors of the Vocal Cords with Specimens, Hal Foster, M.D., Kansas City, Mo.
 2. Self Tied Knot in a Funis, A. Bowen, M.D., Nebraska City, Neb.
 3. Appendicitis, from the Standpoint of a General Practitioner, R. M. Stone, M.D., Omaha, Neb.
 4. Pelvic Surgical Disease and Complications, How Dealt with, A. H. Cordier, M.D., McPherson, Kans.
- 10:30—Banquet at the Lindell.
- Second Day.*—9.00 A.M.—Report of Committees.

Presentation of Papers.

1. Removal of Faucial Tonsils by Galvano-Cautery Snare, H. W. Loeb, M.D., St. Louis, Mo.
2. Treatment of Fractures of Humerus. Report of Twelve Cases, Joseph Neville, M.D., Omaha.
3. Tubercular Knee-Joint Inflammation, with Specimens, A. F. Jonas, M.D., Omaha.
4. Rheumatism, S. Lane, M.D., Lincoln.
5. Synopsis of Etiology, Pathology and Treatment of Sciatica, S. Grover Burnett, M.D., Kansas City.
6. Appendicitis, treatment of, with Illustrative Cases, J. E. Summers, Jr., M.D., Omaha.
7. Pathological Tonsil and its Relation to Nasal Drainage, F. D. Crim, M.D., Lincoln.
8. The Irritable Mucous Membrane in Gouty Subjects, Wm. Davis, M.D., Omaha.

9. Reflexes due to Hypertrophied Follicles of the Tongue, W. L. Dayton, M.D., Lincoln.

10. New Observations in the Use of Sulphonal, S. G. Burnett, M.D., Kansas City.

Miscellaneous Business.

INDIAN TERRITORY MEDICAL ASSOCIATION will meet in Muskogee, I. T., Tuesday, December 8, 1891.

Section on Practice of Medicine.—"Malarial Fever," S. A. Bryan, M.D., Wagoner, I. T.; "Malarial Hæmaturia," A. M. Clinkscales, M.D., Vinita, I. T.; "Some Advances in Medicine," W. B. Winn, M.D., Wichita, Kan.

Obstetrics and Gynecology.—"Ovarian Hyperæmia and Hæmorrhage," J. M. Boling, M.D., Claremore, I. T.; "Complicated Pregnancy," G. A. McBride, M.D., Ft. Gibson, I. T.; "Chronic Metritis," E. N. Wright, M.D., Lehigh, I. T.

NOTICE.—We are constantly in receipt of letters from physicians stating that they have not received the copy of "The Biography of Ephraim McDowell, M.D.," for which they subscribed through the author, Mrs. Ridenbaugh, and for which they paid in advance at the time of subscribing. As in these letters we are held accountable for the delay, in justice to ourselves we wish to explain that we are merely acting as publishers for Mrs. Ridenbaugh; that she paid for the printing of the book herself; that we have nothing whatever to do with the delivery of the books; no list of subscribers was furnished to us; we are in no way responsible for the filling of these orders; the book was merely manufactured for Mrs. Ridenbaugh at her expense; she retained the list of subscribers and was to attend to the delivery of the same.

We believe she was engaged in filling these subscriptions when she was taken sick and is just recovering from a long and severe illness, which accounts for the delay.

Any letters addressed to Mr. Louis T. Valentine, Knickerbocker Building, corner 14th St. and 5th ave., New York City, whom Mrs. Ridenbaugh has recently married, and who is managing the sale for her, will be given prompt attention. CHAS. L. WEBSTER & Co.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from November 21, 1891, to November 28, 1891.

Capt. Marlborough C. Wyeth, Asst. Surgeon U. S. A., leave of absence granted on surgeon's certificate of disability is extended three months, with permission to enter the Army and Navy General Hospital, Hot Springs, Ark.
Capt. William R. Hall, Asst. Surgeon U. S. A., granted leave of absence for twenty days.
Capt. Arthur W. Taylor, Asst. Surgeon U. S. A., leave of absence granted for seven days is hereby extended twenty-three days.
Capt. Marshall W. Wood, Asst. Surgeon U. S. A., is granted leave of absence for three months, with permission to apply for an extension of one month.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending November 28, 1891.

Middleton Semmes Guest, commissioned an Asst. Surgeon in the Navy November 19, 1891.
Surgeon Wm. Martin, ordered to the U. S. S. "Thetis."
Asst. Surgeon Geo. B. Wilson, detached from U. S. S. "Thetis," and granted two months' leave.

STUDIES OF CRIMINALS.

DEGENERACY OF CRANIAL AND MAXILLARY DEVELOPMENT IN THE CRIMINAL CLASS, WITH A SERIES OF ILLUSTRATIONS OF CRIMINAL SKULLS, AND HISTORIES TYPICAL OF THE PHYSICAL DEGENERACY OF THE CRIMINAL.

Read in the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY G. FRANK LYDSTON, M.D.,

Professor of Genito-Urinary and Venereal Diseases in the Chicago College of Physicians and Surgeons; Fellow of the Chicago Academy of Medicine, and of the Southern Surgical and Gynecological Association, etc.,

AND E. S. TALBOT, M.D., D.D.S.,

Lecturer on Dental Pathology and Surgery, Rush Medical College; Fellow of the Chicago Academy of Medicine; Member of the Odontological Association of Berlin, etc.

The mutuality of interest involved in their studies of the degenerate classes, has led the authors of this paper to combine their observations in a joint paper. This paper, however, is too lengthy for presentation to this Section. We have, therefore, abridged the subject-matter as far as possible, with the view of presenting only the most important features of the essay, reserving its complete publication until some future time.

The present paper comprises a portion of an address upon "The Skulls of Criminals," with cuts of the more important specimens, delivered by Dr. Lydston, at the meeting of the Mississippi Valley Medical Association, September 11, 1890, together with some of Dr. Talbot's studies of the jaws of the degenerate classes, and deductions drawn from an extensive series of coöperative studies of criminals. No attempt has been made to formulate an arbitrary theory regarding the crime class. Indeed, it is the opinion of the authors that even the extensive researches of Lombroso, Ferri and others, have been insufficient in this respect. We advance the proposition—which is itself not a new one—that the crime class is simply a part and parcel of that human flotsam and jetsam which can be so aptly termed the world of degeneracy.

We give due credit to Lombroso, Ferri, Benedikt, Osler, Mills, Roussel, Badik, and numerous

other workers in this field, and are free to acknowledge that we do not hope to add much to what these eminent men have contributed upon this subject.

Very little has been done in America in the study of criminal anthropology. Nothing whatever has been done in the study of the degenerate development of the jaws as exemplified by the criminal class, hence our contribution to the subject may be of interest.

C. Lombroso, of Italy, has done most wonderful work in the study of the criminal classes. His "L'Homme Criminel" is justly regarded as a classic upon this subject. There is one point, however, in regard to his observations, that is worthy of serious consideration, viz.: it is to be remembered that he has collated his material in an environment entirely different from that in which the American criminal is found. This fact will explain the diversity of opinions regarding the crime class as observed here and in Europe. As Dr. Lydston pointed out in a paper on "The Pathogeny of Vice," published some years ago, the results of evolution and atavistic tendencies are necessarily more pronounced in the offscourings of the older social systems as met with in Europe. Our observations tend to show that the more pronounced criminal types, as seen in this country, are among the imported criminals.

The aberrant brain types as seen among the degenerate classes, and so excellently described by Benedikt, C. K. Mills and others, do not concern us in the present paper, save in a general way. As far as the specimens which we present are concerned, it is rational to suppose that an aberrant brain was present in each of the deformed skulls of our series. While external conformation is not an accurate criterion of brain development, it is still logical to suppose that when a skull is malformed through degeneracy, its contents are also involved in the maldevelopment, and from similar causes. There is often, however—and, according to Biliakow—especially among criminals, an entire lack of harmony between the external and internal measurements. Oftentimes the external circumference—especially in the frontal and occipital regions—is greater than the normal average, while the internal cir-

cumference is notably diminished. In case the relative deformity of the skull is due in a measure to an increased thickness of bone, much depends on the disposition of the increase, *i. e.*, on whether it is uniform, involving both tables of the bone, several bones, or is due to excessive development of external bosses. Lombroso advances sclerosis as an explanation of diminished cranial capacity when associated with large external measurements. The relation of syphilis to a disparity of the internal and external measurements and conformations is at once called to mind.

Other things being equal, the internal conformation is certainly a fair criterion of cerebral development; it is most positively an accurate criterion of cerebral conformation.

We wish to be clearly understood as recognizing perfectly the fallacy of arbitrary conclusions regarding cerebral development founded upon osseous conformation. As is well known, even the relative size of the cerebral mass itself has no definite and arbitrary relation to intellectuality. The old familiar illustration of the comparative measurements and weights of the brain of Daniel Webster and that of an idiot immediately suggests itself at this point. Spitzka has recently exhibited the brain of an idiot which weighed 68 ozs., but in which the endyma was five times its normal thickness.

In the collection in the Army Medical Museum is a specimen which aptly illustrates the inaccuracy of the size of the brain as a criterion of intellectual capacity. This is the skull of a Chipewa squaw, of dwarfed and degenerate physique, who died at the age of 85. The stature of this subject was but 3 ft. 7 in. The skull measured 633 mm. in circumference, and presented a capacity of 2,760 cn. cent. The facial angle is 105°. The brain weighed 73.5 ozs.

The vertical index in this specimen is platycephalic, the horizontal brachycephalic. The occipital plane is almost horizontal, the parietal eminences extraordinarily developed. The facial bones present an arrest of development; the inferior maxilla is square, excessively developed and prognathous, the teeth are degenerate. These points are interesting as showing excessive maxillary, arrested facial and excessive cranial development in the same subject. The association of the defective structure in this specimen with disease is suggested by the fact that the subject had suffered with caries of the spine.

The variations of type of the degenerate brains of criminals and the insane, as shown by Benedikt, Osler, Roussel, Lombroso, Parker and C. K. Mills, embrace briefly: variations in number, length and development of convolutions, the question of length of gyres being of special importance. Simplicity of type of gyres seems to be indicative of degeneracy. Dr. C. K. Mills has

presented this subject in a very plain and comprehensive manner.¹ The researches of this author will be quoted in detail when the present paper is published in its entirety.

In one of Dr. Lydston's specimens (Fig. 24), the degeneracy of brain type is shown by the shallowness of the cranial fossæ and feeble development of the ridges, lines and prominences of the interior surfaces of the skull. In a general way the same may be said of all the other specimens of the series, those which are not imperfectly developed being excessively developed in varying localities.

Criminal anthropologists lay great stress upon the capacity of criminal crania. Tabular comparisons of large numbers have shown some very interesting points. According to Lombroso, the maximum of cranial capacity is met with in counterfeiters, the capacity in this class varying in different localities, but with two exceptions being greater in each locality than that of other criminals. Murderers and brigands are next in the scale. Thieves of the petty sort follow with a mediocre capacity, while the lowest is found among violators and incendiaries. These estimates are about what might naturally be expected in the various grades of criminality. The type of criminality varies with the degree of intellectual development, and the latter depends to a certain degree upon physical conformation. The tables of E. Ferri confirm Lombroso's deductions. He finds the greatest capacity among those convicted of assault, the smallest among pickpockets and professional assassins. Criminals who have been repeatedly convicted (*recidivistes*) present, according to Ferri, a smaller cranial capacity and frontal diameter, with a larger development of the jaws than the average normal subject. The researches of Baroffio, Riva, Troyski, Roussel, Corré, Biliakow, Manouvrier and others, are practically in accord with Lombroso and Ferri.

As compared with the researches of such investigators as those mentioned, our observations have been of a very general character, and we have as yet been unable to obtain a sufficiently large series of measurements to permit of a tabulated comparison of normal and criminal crania. We have observed, however, many facts which appear to us of great interest, drawn from the study of criminals confined in a number of our penitentiaries.

The most striking features of the criminal skull as seen in American prisons, are the tendency to brachycephalism and sub microcephaly, and the great frequency of cranial asymmetry. As far as our observations go, they tend to show that a degenerate type of skull is common among criminals, and that the assertion of Lombroso that the deviation of type, as far as the index is con-

¹ Transactions of the American Neurological Association, 1886.

cerned, is toward brachy-cephaly, is correct. The broad head is usually associated with a relatively low vertical index, *platy-cephalic*; the long head with a high vertical index, *oxi-cephalic*, which, however, is more than compensated for by the long transverse diameter in the one and the narrow transverse diameter in the other (Figs. 24 and 33).

The direction of degeneracy is modified by racial characteristics. Thus in the case of the Chinese, characterized by a relatively high index, the tendency of degeneracy seems to be in the direction of a more pronounced brachy-cephaly, although an occasional example of the opposite index is seen. The dolicho-cephalic type, when degenerated, becomes in general more dolicho-cephalic, etc.

In considering the degree of degeneracy the question of compensating increase or decrease of diameter must be considered as affecting capacity. A glance at the original of Fig. 33 while living would doubtless have suggested a capacious cranium, but a measurement of the vertical and frontal diameters puts an entirely different complexion upon the status of the subject as indicated by cranial capacity. A glance at Fig. 24 shows a cranium which to a superficial observer might appear to have considerable capacity. Yet it is ultra-brachy-cephalic, and even a proportionally exaggerated vertical diameter does not redeem it from sub-micro cephalic.

A striking feature of the degenerate skull as illustrated by many skulls in the habitual criminal class is its peculiarly twisted conformation. The form suggests what might result if the skull were taken while soft between the hands and twisted in such a manner that all points of anatomical correspondence are thrown out of their normal relations. The result would naturally be an asymmetry in all diameters. Figs. 34 and 35 show this most admirably.

The researches of Dr. Talbot in the jaws of the degenerate classes have been of extraordinary interest, and are rendered even more interesting by our joint observations of the jaws of a large number of criminals. The types of degenerate maxillary development are well shown by the appended drawings prepared by Dr. Talbot, and will be expatiated upon later on.

Lombroso, Ferri and Manouvrier claim certain peculiarities of development in the criminal jaw. Exaggerated development, preëminently among homicides, is the especial feature commented upon by Lombroso. Ferri has found the greatest diameter of the jaws among homicides and petty criminals, the smallest among professional murderers and pickpockets. The jaws according to Ferri are not well developed among the insane, save those who are the subjects of impulsive monomania. This does not agree with Dr. Talbot's observations.

In our studies of criminals we have found that the most marked variations from the average normal type of cranial development occur among the habituals. We have made no attempt to select special cases bearing out this assertion, but have studied each case as it has been taken at random. We append a series of observations upon criminals, selected by a convict orderly from among the habituals and murderers in the Joliet penitentiary. In reply to his inquiry as to what kind of cases we wished to study, we remarked that we wished to see old-timers or habituals. He therefore selected the prisoners according to their criminal, with an entire disregard of their physical status, with the possible exception of several who happened to be on sick call. All complaints of subjective ailments were verified by the resident medical officers.

We present the history and description of eighteen of these, taken in regular order:

Obs. 1.—White, male, American, aged 30 years. Has been committed twice for burglary. Was first committed at the age of twenty-two, since which time has been a confirmed criminal. Hereditary influences as a possible cause of delinquency not probable. Intemperance is admitted and is claimed to have had much to do with his moral degradation, and as he is markedly neurotic, this is highly probable. Syphilis is denied. Never experienced an injury until two years ago, when he received a severe fall with contusion of the head. This was followed by epilepsy, severe headaches, insomnia, deafness, defective vision in the right eye and pronounced right hemiplegia. Hearing normal. Mentality impaired. He is thin, anæmic and badly nourished. Was formerly right-handed but has acquired left-handedness since the accident.

The jaws, especially the inferior, are quite asymmetrical and the nose deflected, not from traumatism. Features very asymmetrical. Ears small, protuberant, pointed and asymmetrical, the left being the larger and more prominent. The septum nasi is thickened and greatly deflected. Cranium of medium development, of sub-brachy-cephalic type and rafter shaped calvarium. Jaw, orthognathous. Occipital region very prominent and asymmetrical, the protuberance being markedly deviated to the left of the median line. Pronounced asymmetry of parietal development, the left eminence being very prominent and the right perceptibly flattened. Palate imperfectly developed with a V-shaped arch.

Obs. 2.—White, male, Irish, aged 27 years. Sentenced for arson. Committed for the second time, the first offense being robbery. Has led a criminal life since childhood, being addicted to petty and minor delinquencies for which he escaped punishment. Knows nothing of his parentage or family. Has never been addicted to drink. Admits syphilis. Is thin, anæmic and

poorly nourished, says that he was never very strong. Right handed. No lameness or deformity. Slightly deaf. Vision normal. Perceptive faculties somewhat blunted and mental processes sluggish. Is a melancholiac and suffers from severe headaches. Features noticeably asymmetrical. Nose perceptibly deflected and flattened, not traumatically. Septum thick, crumpled and on the right side enchondromatous, the right nostril being occluded. The ears are peculiarly deformed, the right being small, thick and crumpled, the left of medium size and very protuberant, handle shaped. Cranium large, ultra-brachy-cephalic, with platycephalic vertical index and resembling in its general outline the skull shown in Fig. 33. To the left of the vertex the calvarium is flattened, but the left parietal protuberance is very prominent, the entire left side bulging in outline. The right side is flattened and the parietal prominence slightly marked. The body of the occipital bone is very straight and flat, but the protuberance is proportionally prominent. The facial outline is orthognathous, the jaw being of a pronounced retreating type and very asymmetrical. Palatal arch V-shaped.

Obs. 3—White, male, American, aged 40 years. Serving second sentence for burglary. Prior to first commitment had been sentenced for numerous petty delinquencies and had been tried on charges of burglary and acquitted on several occasions. History shows a bad heredity. Mother healthy, but father died of consumption and a sister is subject to fits. Has been addicted to liquor. Says that liquor is responsible for his life of criminality (?). Contracted syphilis eighteen years ago, which has troubled him off and on ever since. General appearance very fair, is well nourished and of good color. Right-handed. No lameness or deformity, but plentifully supplied with syphilitic scars. Is quite deaf and vision is so defective that he reads with difficulty. Suffers from tinnitus aurium. The facial contour of this man is very striking. There is such a marked disparity and asymmetry of the two sides of the face that it has the appearance of two halves of faces of different sizes joined together, and by a bad artisan. Nose deflected markedly and septum twisted and mal-formed so that the left nostril is completely blocked. The ears are very asymmetrical and situated on different planes, the right ear being much the smaller and situated several lines higher than the left.

Cranium sub-microcephalic and very asymmetrical. The right side of the cranium is very perceptibly flattened and the parietal prominence feebly marked. The left prominence is very marked. The forehead is low and retreating. The narrow and contracted skull in this case is directly noticeable, but the index is sub-brachycephalic on account of the markedly sloping

frontal region, which compensates in a measure for the narrow transverse diameter. The facial type is orthognathous. On examining the mouth, a high palatal vault of partial V shape, with pronounced saddle contour on the right and full curve on the left, are noted. There is marked faucial and pharyngeal asymmetry. There is a lateral curvature, which accounts, in a measure, for the pharyngeal and faucial deformity.

An interesting feature of this case is that the subject suffered from constant and severe headaches until fifteen years of age. They then stopped, but were developed later in life by liquor. Has had them steadily for the last fifteen months and is suffering from insomnia—possible pachymeningitis syphilitica or alcoholica suggests itself in this connection.

Obs. 4.—White, male, German extraction, age 41. Serving time for murder. This case is most interesting as an example of illogical dispensation of law and of the physical basis of crime. The subject is typically neurotic; heredity bad, mother having died of cancer, and her branch of the family being subject to various forms of nervous disease. Cause of father's death unknown, but he was known to have been a dissolute character. The subject under consideration was struck in the head with a hatchet when a child. Since the age of eight he has had epilepsy, the fits occurring sometimes every three or four days and at others at very long intervals. Has at times escaped them almost entirely for a year or two and has then brought them on by indulgences in liquor, to which he was addicted; subject to violent paroxysms of fury at all times under slight provocation; has been committed to the asylum several times; history would seem to point to the furor epilepticus as a cause for the murder which this man committed. A noteworthy fact is that this man is very artistic and spends much of his time in making artificial flowers. Syphilis is denied and no evidences of the disease are perceptible; subject is pale and anæmic; is right-handed; vision normal, but is quite deaf in left ear; no deformity or lameness.

Features very asymmetrical, the right side of the face being much larger than the left. The nose is markedly deflected to the left, the septum being thickened, crumpled and deviated in the same direction. Ears very asymmetrical, the left being the larger, higher situated and badly formed. The right ear is very protuberant, imperfectly developed and crumpled.

Cranium of medium size, quite round and dome-shaped. Vertical index oxycephalic. Index markedly brachycephalic. The skull shows the same asymmetry as the face, the right side being disproportionally developed and the right parietal eminence very large. The left side is flattened and the parietal prominence barely

distinguishable. The arch of the jaw in this case is normal, but the development of the palate is defective and the rami defective in development.

Obs. 5.—White, male, American, aged 37. Committed for the third time for burglary. Family history unknown save as regards mother, who died of cancer. Has had syphilis and has been intemperate since youth. Was hurt in a railroad accident in 1881. Prior to this time he had worked tolerably steadily, but since the accident he had drank harder than ever and had developed an uneasy, restless disposition, which made honest labor irksome and criminality attractive. General appearance fair, is well nourished.

Right-handed and has no lameness or deformity. Complains of tinnitus in the right ear, referable he thinks to the railroad accident. Vision and hearing normal. Face very asymmetrical, the right side being much the larger. Right

Fig. 1.

malar prominence exceptionally marked. Left eye so disproportionately small as to attract the attention of the casual observer. Nose deformed and septum deviated to the left, but as the organ has been broken this point is not of great importance. Ears very small, crumpled and closely set, the left being much the larger and lower.

The skull is sub-micro cephalic in capacity, oxy-cephalic in its vertical and brachy-cephalic in its cranial index. The right half of the cranium is the smaller, with the exception of the right occipital and mastoid regions, which are excessively developed. The left parietal eminence is very prominent. None of the aberrations noted were referable to the injury, except possibly the nasal deformity. The superior maxilla is V-shaped.

Obs. 6.—White, male, Irish, aged 50. Serv-

ing a five year sentence for horse stealing. Served a six-year sentence twenty years ago for the same offense. Acknowledges repeated offenses for which he has never been punished.

Family history not clear, but says that father died of old age and mother of "fever sore" on her leg; has been intemperate since youth and has had severe syphilis; has had severe small-pox, with resulting great disfigurement, not shown in the cut; general appearance fairly healthy; is very awkwardly built, "slab-sided," as the orderly expressed it; his gait is of the shuffling or shambling variety; is right-handed; is lame as a consequence of syphilis; hearing normal; vision has been impaired for many years; features very asymmetrical; the face is long and narrow and the chin pointed, but not prognathous; the left eye much smaller than the right, not properly shown in cut and the entire left side of the face imperfectly developed; the nose is slightly flattened and the septum deviated to the

Fig. 2.

left, the nostril being nearly occluded; the ears are asymmetrically developed, the left being the larger, most thickened, irregular and deformed; cranial index brachy-cephalic; vertical index platy-cephalic; the large size and disproportionate breadth of the cranium are very noticeable.

The cranium is asymmetrically developed. The right frontal eminence is very prominent. The left parietal prominence is very large. The calvarium is depressed at the right of the vertex. There is also a well-defined depression at the bregma. The right occipito-mastoid region is excessively developed. The generally twisted appearance of cranium already alluded to is well shown in this subject. The jaws are saddle-shaped and the palate irregular and unevenly developed.

The actions and garrulous conversation of this subject showed him to be a paranoiac of a pro-

nounced type. A glance at the physiognomy of this man, as shown in Fig. 2, is suggestive to the neurologist in this connection.

Obs. 7.—White, male, American, age 53. Sentenced for horse stealing. Had several sentences elsewhere and is serving a second term in Joliet. Family history not obtainable; had been occupied in farming and horse dealing, alternating with horse stealing most of his life; no history of syphilis or alcoholism; general appearance bad, pallor and cachexia being pronounced; is right-handed; presents no lameness or deformity; vision and hearing normal; the features are very asymmetrical; the nose is quite straight, but the septum is deviated to the left, producing partial occlusion; the eyes are small, deep-set and somewhat of the slanting type peculiar to the Mongolian. This peculiar slant is most evident upon the right side; the right eye is also smaller

Fig. 3.

and on a higher plane than the left. The difference in development of the two sides of the face is very marked, the right being the smaller. The left half of the inferior maxilla is much longer and straighter than the right. Hair has been very gray since quite a young man. The right ear is of moderate size, of fair form and very closely set—the left is flattened, flabby and protuberant, “handle-shaped” and lower than the right.

Cranial capacity is meso-cephalic and cranial index subbrachycephalic. The vertex is pointed, oxycephalic with marked depression upon each side of the median line. The left occipito-mastoid region is exceedingly prominent, the right being deficiently developed. The left parietal eminence is very prominent and the right poorly marked. Semi-V-shaped superior maxilla, lower maxilla well developed. The subject is an apt illustration of the irony of fate and the unintelligent administration of law. He is a par-

anoiac and affected with monomania of the religious delusional type. At times imagines himself Jesus Christ. He preaches in his cell to imaginary spirits, over which he imagines that he has control, and regales his fellow convicts with an occasional sermon on their wicked ways. His conversation is characterized by egotistical garrulity; is particularly desirous of impressing us with the idea that his magnificent head was designed for some great purpose which “died a-bornin’.” Like the preceding case, the physiognomy of this subject is to the alienist confirmatory of the foregoing remarks. Fig. 3.

Obs. 8.—White, male, Swede, aged 30; up for larceny, second conviction and acknowledges offenses for which he was never punished; has worked at different trades and occupations, but labored steadily until he received the injury herewith described. Family history obscure; mother had some skin disease of a severe type; has been a moderate drinker; syphilis is denied; general condition fair; is somewhat anæmic; is right-handed; some years ago was caught in a railroad smash-up and sustained a fracture of the skull; several years ago had his arm caught in machinery and received a compound fracture of the forearm; was in hospital seven months.

Hearing greatly impaired; vision normal. The face is very asymmetrical, the right side being the better developed, and the right half of the jaw especially prominent; nose of normal type; no deflection of septum; ears very asymmetrical, the left being larger and more closely set and decidedly pointed; the right is of medium size and normal outline, but situated lower than the left; jaws square and well formed, but the hard palate is very asymmetrical; left palatal process much broader than the right.

The cranium is large, horizontal index brachycephalic; vertical index platycephalic; the frontal region is asymmetrical, the right prominence bulging decidedly; the parietal prominences are exceptionally well marked, the left being much the larger; the entire right half of the cranium is disproportionately well developed, with the exception of the parietal eminence; depression at site of old injury in parietal region. This subject, like the foregoing, should not be in prison. He is a paranoiac—has delusions of persecutions, quarrels with imaginary enemies in his cell and has on one occasion attempted suicide by cutting his throat.

Obs. 9.—White, male, American, aged 59. Fourth commitment; offense, horse stealing; committed three times before on “general principles;” does not deny that said commitments were for the public good; heredity bad; father died of cancer of the stomach, mother was insane and died of consumption; says he does not give a “fake” history for the purpose of exciting sympathy—says his motto is: “Sympathy be d—d!”

Has never been intemperate—says that he feared to drink on account of the insanity in his blood; syphilis is denied; had his head cut by a rock in Chester penitentiary years ago.

General appearance quite bad; is anæmic and poorly nourished; was originally right-handed, but on account of lameness in joints of right hand, has acquired the use of left; left arm is also lame from injury; joints are generally crippled by arthritis deformans; vision presbyopic; hearing normal.

The face is very asymmetrical, the right side being the larger; nose malformed and deflected to the right; septum deflected and presents a large perforation; ears of average development and symmetry; right ear a little lower than left; dental arches normal but inferior maxilla greatly flattened at angles and quite asymmetrical; cranium of average development; sub-brachy-cephalic index. Since the injury to his head this man states that he has "wild spells" when his mind is aberrated. These "spells" follow severe headaches.

This man, although uneducated, is quite talented, very bright and logically argumentative. His moral obliquity is evidently due to a bad heredity and lack of mental discipling. Under more favorable auspices he would have made a valuable member of society.

Obs. 10.—White, male, German, age 31. Serving sentence for grand larceny. Has been in prison five times, this being his third term in Joliet. Heredity bad; father healthy but intemperate, quarrelsome and subject to violent fits of passion, which made him a "dangerous customer" at times. An only brother, though honest, is intemperate and a ne'er-do-well. Paternal grandfather said to have been a martyr to scrofula; has not been intemperate; syphilis denied, but states that he was very scrofulous as a child; extensive scrofulitic scars visible on neck and face; is still quite sickly, looks cachectic and badly nourished; is right-handed; no lameness or deformity; vision and hearing normal; facial asymmetry quite marked, the right side being much the larger. The nose is markedly deviated to the left and the septum much deformed and deviated to the right, producing almost complete occlusion. The left palpebral fissure much smaller than right; left eye perceptibly smaller than right; ears fairly symmetrical and well formed; cranium very large, index ultra-brachy-cephalic, vertical index platy-cephalic; fair degree of symmetry; left parietal eminence very prominent.

This subject has been affected with severe stammering since childhood; is frequently under treatment for severe cephalalgia and has had since childhood what he terms "dumb spells," which we interpret as mental depression, probably associated with disturbed circulation.

The inferior maxilla in this case was poorly developed, orthognathous and very pointed; upper jaw presents a marked saddle-shaped arch.

Obs. 11.—White, male, Swede, age 27. Acknowledges habitual criminality, though serving first sentence; is in for highway robbery; heredity not shown; mother died of dropsy, and father of pneumonia; intemperance and syphilis both admitted; no history of injury; general appearance fair; right-handed; somewhat lame in left leg—thinks that always was weak in this limb; vision and hearing normal; face asymmetrical, left side much the larger—left side of the lower jaw being extraordinarily prominent; left palpebral fissure and eyeball much larger than the right; nose deflected to right, with marked corresponding deviation of septum; ears very large, long, pointed and closely set; cranium sub-microcephalic with sub-brachy-cephalic index; oxycephalic vertical index.

Development of average symmetry. In his general characteristics this subject is a weakling and the crime for which he is doing time is inconsistent with his physique.

The jaws in this case are markedly deformed, the upper presenting a semi-V and the lower a marked saddle.

Obs. 12.—White, male, half-breed Egyptian, age 35. Serving sentence for horse stealing. Says that it is his first commitment, but his statements are contradictory and he has either been committed before or has led a criminal life without punishment; the family history is imperfect, as he was born in Egypt of a native mother and an American father. One brother is known to be insane but not criminal; has drank periodically after he has had one of the "fits," to be described; syphilis denied; when quite a young man he enlisted in the American navy and served for some years; was finally discharged for disability, having been sunstruck while in the foretop, falling to the deck and sustaining severe head injuries, the scars of which still remain. After his discharge he suffered from epileptic fits at intervals of from a few days to a few weeks; is still suffering from these attacks and from severe headaches; criminal career began since injury (?).

General appearance excellent; right-handed; no lameness or deformity; head badly scarred from old wounds; vision and hearing normal; face fairly symmetrical; eyes equally developed; right side of face slightly the larger; nose not deformed, but septum deviated to the right with partial occlusion of nostril; ears very small, closely set and crumpled.

Cranium large and index sub-brachy-cephalic; development asymmetrical; right side much the larger; occiput unequally developed, right half being very prominent, left parietal eminence very large as compared with the right; jaws normal.

Degeneracy of physical type is not very pronounced in this subject. We consider the history of injury a very important point.

Obs. 13.—White, male, American, aged 26. Committed for the first time for forgery; acknowledges petty delinquencies before sentence for forgery; family history bad; father delicate, scrofulous and affected all his life with sore eyes; mother died of consumption; has been a steady but moderate drinker; syphilis denied; general appearance good; right-handed; vision and hearing normal; face quite asymmetrical, left half much the larger; left eye much smaller than the right; nose straight and symmetrical, but septum markedly deformed; ears symmetrical, but very small and closely set; cranium of medium size and asymmetrical; index meso-cephalic; left occipito-parietal region disproportionately developed; right half of occiput flattened; protuberance situated seven mm. to the left of the median line; left parietal eminence very prominent.

Facial development marked; pronounced prognathism of inferior maxilla.

Obs. 14.—White, male, Irish (typical imported criminal), aged 54; in for bank robbery on long sentence. This is one of the toughest specimens that ever broke into jail; he has done time in a number of prisons in America and served several sentences in England before being exported to this country by the generous British authorities; family history bad; father intemperate; both parents died of consumption while subject was very young; one brother died of consumption; has always been a hard drinker; has had syphilis; general appearance very bad, is thin, sallow and badly nourished; has a chronic cough; is somewhat crippled by rheumatism, otherwise no lameness or deformity; hearing normal; vision impaired by age; face very asymmetrical, left side being disproportionately developed; left eye perceptibly the larger; right frontal prominence, however, is bulging and prominent; nose badly deformed, septum enchondromatous and deflected and so badly deformed that it is visible externally; ears very prominent and pointed, the left is badly crumpled.

Cranium sub micro-cephalic; index sub-dolicho-cephalic; fairly uniform development on each side, but right side much the larger.

Lower jaw small, prognathous and left half much the larger; upper jaw large with low arch.

Obs. 15.—White, male, Dane, aged 42; serving life sentence for murder; family history good; has never been intemperate and until the commission of the crime for which he is under sentence he was an honest hard-working farmer, distinguished only by a violent temper; the murder for which he is doing time was the result of a quarrel; has never had syphilis; general appearance excellent; right-handed; vision

and hearing normal; no lameness or deformity; features asymmetrical, the preponderance of development being on the left side; nose deformed and deflected to the right; septum shows a corresponding deflection; ears asymmetrical, the right being pointed, closely set and of medium size, the left large, protuberant and lower set than the right.

Cranial capacity meso-cephalic; index sub-brachy-cephalic; pronounced asymmetry, the left side being the larger, the development of the left occipito-parietal region being especially disproportionate; the right parietal eminence is much larger than the left; the forehead is low and retreating; frontal prominence slightly marked on left side and absent on right; upper jaw excessively developed and prominent; arch semi-V shaped; lower jaw prognathous and heavy and disproportionately developed on the left side.

Obs. 16.—White, male, American, age 42. Serving a life sentence for a murder which had been committed in a quarrel. Prior to this crime had been an industrious farmer. Family history unknown; alcoholism and syphilis denied; general appearance fair; right-handed; no lameness or deformity; is lame at times from rheumatism; vision impaired; hearing normal; nose well shaped; no deflection of septum; ears small, thin, and closely set; cranium above the average capacity and fairly symmetrical; index brachy-cephalic; some flattening at the bregma and in the occipital region; upper jaw excessively developed and partial V-shape; lower jaw massive and prognathous.

Obs. 17.—White, male, age 17. This is one of the most melancholy cases which have come under our observation. The prisoner, a bright, handsome boy, having been sentenced for life for a murder committed while under the influence of liquor. The lad was raised on a farm and his family history is unexceptionable. Habitual intemperance denied; no history of syphilis; general appearance excellent, but subject is plainly neurotic; is right-handed; no lameness or deformity; vision and hearing normal; facial development quite symmetrical save a little excess of development of the right half of the inferior maxilla; nose slightly deviated, with some deflection of septum; ears large and protuberant (*oreilles à anse*); capacity of cranium meso-cephalic. Practically no asymmetry, the form of the cranium being better than the average normal type. The lower jaw is asymmetrical as above noted and the upper jaw presents a partial V.

Obs. 18.—White, male, American, age 61, doing time on fourth commitment. Last offense burglary and arson. Family history unknown. Was evidently a vagabond in early life but was never convicted of crime and he states was never

delinquent until 1871, since which time he has been in jail off and on—in fact for the greater part of the time. Intemperance and syphilis is denied. Drifted into the army in his early manhood and was several times wounded. Is lame from a saber cut in the left leg and head shows a large scar from a saber cut received in '63.

General appearance excellent; vision and hearing normal; right handed; has been gray for many years; face fairly symmetrical; nose slightly deflected, but septum well formed; ears well formed; cranial capacity meso-cephalic; index brachy-cephalic; asymmetry not very pronounced; left parietal eminence disproportionately prominent; occipital region exceptionally flat; mastoid prominences excessively developed; normal arch in upper jaw; lower jaw very prominent, heavy and prognathous.

The foregoing cases might be multiplied from the material at our command, but they are amply sufficient as indicative of what may be found among the degenerate classes met with in our American prisons. A glance at these cases plainly shows the physical degeneracy, and often the bad heredity of the subjects. A noteworthy fact is that the cases which most nearly approximated the normal type of development were in sporadic criminals, of which the young lad (Obs. 17) is an example. It will be noted that a number of the series were of foreign birth. As before remarked, it will be found that the most markedly aberrant types are seen in the imported criminal. This is instructive as explanatory of some of the apparently dogmatic claims of European criminal anthropologists. We have found that left-handedness is not so common among American and foreign American criminals as has been claimed by these authorities. Among 400 criminals in the Joliet penitentiary but one per cent. were found to be left-handed. Dr. Lydston found but about two per cent. among the criminals in the New York City prison. Obviously a much larger number of observations would be necessary to determine this point.

Regarding deviations of the form of the nose, ears, etc., we are well aware that these aberrations of development are frequent among normal individuals, or at least those reputed normal. We do not believe, however, that so large a proportion is observable in normal as in criminal subjects. It is to be remembered, moreover, that degeneracies of development are present in many otherwise normal subjects, whose *morale* is such that no delinquencies have occurred. We have nothing to do with the co-relation of criminal tendencies with osseous aberrations save in a general way, *i. e.*, we advance only the proposition that *ceteris paribus*, cerebral degeneracy is to be expected in cases where the osseous framework is markedly aberrant. The same influences govern the development of both nerve

and bone tissue, hence like results are to be looked for.

The history of alcoholism in criminals is to be studied very carefully. "I was drunk when I did it," is the old familiar plea, and to be taken *cum grano salis*. Alcohol often develops inherited or innate acquired tendencies; seldom, in our opinion, is it a cause of criminality, *per se*. It is the touchstone—the crucial lymph—that brings out the inherent infection of madness, crime or bestiality. Heredity is the latent power, and alcohol the potential energy that drives the arrow to the mark.

Very little has been written upon the subject of aberrant development and asymmetry of the skeleton. In looking up this subject a few years ago in the medical library at Washington, only twenty-four cases could be found in foreign and American literature. The only work treating upon this subject has lately been issued by Dr. Sutton, of England, and this but elementary in character. It is a singular fact that, in the study of the defective classes, the attention of scientists has been almost wholly confined to the study of the brain. The most interesting portion of the subject, asymmetry of development of the osseous framework, has been almost entirely neglected. The study of the development of the bony structure through the medium of the defective classes, opens up a field for investigation which is decidedly interesting. That the brain is defective in the flotsam and jetsam of humanity, has come to be generally accepted. The question now is, "Does a defective brain influence the development of the tissues of the body, or is it coincidental with defective development in general, and if so, to what extent?" We must assume that if the tissues in one part of the body are affected by faulty nervous structure, the tissues in other parts may also be affected. We must also assume that if the tissues on one side of the body are arrested in their development, as a consequence of trophic derangement, the tissues of the opposite side may also be arrested or excessively developed from the same cause. It is more difficult to observe this asymmetry of development of the body in general, because of the distance of the parts from each other, than to observe the inequalities of the cranium and maxillæ. Here we have the lateral halves in such close proximity that even a casual glance by an accustomed eye will recognize the smallest deviation in the bones of the head, face and jaws. We would naturally, therefore, select the cranium and maxillæ for an accurate examination.

In the degenerate classes in general, there is a certain degree of similarity of aberrations of type of cranial development. In idiots and the insane, as well as in the habitual criminal, we observe micro cephalic as well as macro cephalic crania. In such cases the jaws may become well devel-

oped or arrested, according to the degree of the development of the skull, although sometimes independent of it. Asymmetry is very marked in these individuals, especially in the hereditary and habitual criminal.

Although prepared to find a goodly proportion of atypical conformations of the jaws and teeth among criminals, our observations gave results which were a little surprising.

There were 477 criminal subjects examined, of whom 468 were males and 9 females. Of the whole number 3 were Chinese, 18 were negroes, and the remainder were whites, the latter representing many nationalities.

The following table shows the different deformities of the jaws and teeth that were found:

DEFORMITIES OF THE JAW AS SEEN IN CRIMINALS.

No.	Sex.	Normal.	Large jaw.	Protrusion Lower jaw.	Protrusion Upper jaw.	High Vault.	V-Shaped Arch.	Partial V-Shaped Arch.	Semi-V.	Saddle Shaped Arch.	Small jaw.	Partial Saddle.	Semi Saddle.
468	Male.	163	66	17	5	70	13	79	19	59	30	92	24
	9 Female	9	9
Percentage.		36.06	15.72	3.56	1.04	14.67	2.70	16.56	3.98	12.36	6.29	19.28	5.03

In the majority of the cases the jaws of the negroes were well developed. One had a partial V-shaped arch, one a saddle, one a V, and in one the left body of the lower jaw was found to be much smaller than the right. The bones of the head and face were also well developed. The three Chinese were all sub-microcephalic, with very small jaws, and two of the three had saddle-shaped arches. It is worthy of note that the nine females examined had large and well developed jaws, with normal arches.

In no part of the osseous system is arrested and excessive development so conspicuous as in the superior and inferior maxillæ. In this region, therefore, we would naturally expect to meet with the aberrations of degeneracy. The reason for this lies in the fact that, while the inferior maxilla is developed independently of the other bones of the skeleton, and attains its normal size by exercise, the superior maxilla, being a fixed bone, is dependent upon the various influences which govern ossification of the bones at the base of the skull, and determine whether such ossification shall be defective, excessive or normal. Some of the causes of aberrant development are inflammation of the parts *in utero*, hereditary taints, eruptive fevers and other constitutional diseases.

It is a singular fact that most of the deformities of the jaws and teeth are confined to the superior maxilla. When deformities of the inferior maxilla occur, they consist in either excessive or arrested development of the bone, while irregu-

larities of the lower teeth are always due to local causes, such as the influence exerted by the irregular teeth on the upper jaw when coming in contact with them in the act of mastication. Deformities of the jaws, as already observed, are more noticeable to the casual observer than deformities of other osseous structures, because they are in closer proximity to each other than the outlines of the lateral halves of the rest of the body, and because any deviation from the normal occlusion of the teeth can be detected at a glance.

The deformities of the jaw proper which we have observed in the criminal classes are fixed and definite in character and few in number, while those of the alveolar processes and teeth

are numerous and variable.

The deformities of the jaw proper consist of excessive or arrested development of one jaw, while the other may be normal, or, one may be over-developed and the other stunted. Sometimes the right side of one jaw will be normal, while the left side will be either excessive or arrested in development. In other cases the two sides will present different forms of development. Again, one may frequently observe a lower jaw with a normal body, while the rami are arrested or excessively developed, or the reverse may be found, *i. e.*, normal rami, with an arrested or excessive development of the body.

Fig. 4 illustrates the condition of excessive development of the upper jaw, as seen in Obs. 14. The jaw, alveolar process and teeth protrude to such an extent that when the jaws are closed, the individual is unable to close the lips.

Fig. 5 illustrates excessive development of the body of the lower jaw, as seen in Obs. 13-18, and in one of the negroes. This deformity is called an "over-bite." The lower teeth protrude and shut outside the upper, which is the reverse of normal occlusion.

Fig. 6 illustrates arrest of development of the rami of the jaw, as seen in Obs. 4. The borders of the alveolar processes, which contain the teeth, are not parallel, and as a result, when the molars make their appearance at the twelfth year, the anterior part of the jaw is forced open.

Fig. 7 illustrates arrested development of the superior maxilla, producing a deformity similar

to that seen in Obs. 13 and 18. There is no protrusion of the anterior superior alveolar process and teeth, owing to the absence of the germs of the lateral incisors and bicuspid, hence these teeth are wanting. The result is that all the superior teeth that are in place, shut inside the lower teeth. When arrest of development of the superior maxilla takes place, and all the teeth are present, two forms of deformity of the jaws and teeth are always observed. The V-shaped arch (Fig. 9), as seen in Obs. 5 and 18, and one of

Fig. 4.

semi-V-shaped arch (Fig. 10), as seen in Obs. 1, 2, 3, 7, 11, 15 and 16, or a semi-saddle-shaped arch (Fig. 11), as seen in Obs. 3, which had a semi-V on one side and a semi-saddle on the other.

The foregoing illustrations represent the types of aberrant development of the jaws and teeth, as met with in the degenerate classes, and can be readily verified by even a superficial examination of the criminal classes. As far as their accuracy as illustrative types is concerned, they

Fig. 6.

the negroes, and the saddle-shaped arch (Fig. 8), as seen in Obs. 6, 10 and 18, and also in one of the negroes. The V-shaped arch is always contracted anterior to the cuspid teeth, while in the saddle-shaped arch the arch is contracted posterior to them.

These peculiar deformities commence to form at about the eighth year, *i. e.*, these deformities are produced while the permanent teeth are erupt-

Fig. 5.

are fairly representative of the various types of deformities as outlined by Dr. Talbot, from a careful study of nearly 4,000 irregularities of the teeth.

It is our fortune to be able to present in this paper a series of illustrations of specimens showing the aberrant types and asymmetry found in degenerate skulls, and especially those of criminals. These specimens are exceptionally interesting from the fact that they have not been se-

Fig. 7.

ing. The reason for this formation is that the long diameter of the jaw is not large enough to contain the long diameter of the teeth. The peculiar variety formed depends upon the time and order of the eruptions. It frequently happens that the teeth upon one side will erupt in their natural manner and at the proper time, in which case the jaw and teeth upon that side will be normal. The other side, owing to premature extraction on the one hand, or on the other to delay in removing the temporary teeth, will form either a

lected from among a large number, but have been picked up here and there by non scientists solely for their morbid and historic interest, having subsequently fallen into Dr. Lydston's hands quite by accident. It is worthy of comment that even the remarkable series depicted in Lombroso's "Atlas" does not present such markedly aberrant types as this comparatively small series of studies; indeed, a search among several thousand skulls would not be apt to bring to light such peculiar types of conformation as the crania

which we present. The illustrations are from photographs, and are exceptionally accurate.

The specimen first to be described is one of the most interesting crania which we have had the privilege of studying. The subject was a negro criminal of the petty class, who spent most of his time in correctionary institutions. As might be inferred from the extremely degenerate type of cranial development which is here exhibited, he

Fig. 8.

was of a very low grade of intelligence. After a very precarious existence, this negro committed suicide.

In viewing this skull from the front, one is at once struck by the immensely powerful maxillary and malar development, as contrasted with the

Fig. 9.

remainder of the cranium. The orbits are relatively very capacious. The superior maxilla is relatively poorly developed, at least as compared with the lower jaw. Rarely, indeed, is such an inferior frontal development found associated with such a pronounced facial development.

As will be seen in connection with the specimen of brachy-cephalic degeneracy shown in Figs. 33, 34, 35, the frontal development in this

narrow type of a skull may be vastly better than some specimens with a decided tendency to the brachy-cephalic type. The skull at present under consideration is the most marked specimen of the dolicho-cephalic cranium which we have seen. As the horizontal index in this case is 59.9, the extreme variation, according to Isaac Taylor and others, being from 58 to 98, the extreme type of this skull is at once obvious.

Fig. 10.

On viewing this skull laterally, its strong similarity to the atthropoids is very striking. This is especially marked with respect to the development of the mastoids and the occipital protuberance; the position of the latter is quite an anomalous one, and the occipital bone is almost horizontal. Despite its extraordinary develop-

Fig. 11.

ment, the occipital is relatively small, both transversely and in its vertical measurement. The distance from the posterior border of the foramen magnum to the superior occipital angle is only 103 mm.

On contrasting with any of the other crania of the series, the relative shortness of the occiput is very noticeable. For example, Fig. 22, which is a rather small specimen, distinguished rather

by the symmetry than by the extent of its development, shows an occiput measuring 130 mm. from the foramen magnum to the superior angle of the occipital bone.

Fig. 14 shows the inferior surface of this dolicho-cephalic specimen, and brings out the massive development of the processes and muscular attachments at the base of the skull. It is evi-

Fig. 12.—Front view of extreme dolicho-cephalic cranium.

dent that the muscles of the neck in this case were immensely powerful, a *sine qua non* where the leverage for muscular action is so short as in this particular occiput. The facial type in this specimen is markedly prognathous, as regards both upper and lower jaws.

Fig. 13.—Lateral view of extreme dolicho-cephalic skull.

The *tout ensemble* in this case is strongly suggestive of a reversion to the anthropoid type, which is often the distinguishing characteristic of the degenerate Ethiopian type, criminal or otherwise.² The following are the measurements of this exceedingly interesting cranium:

² Dr. Lydston has found in comparative studies of crania that the plane of the occipital bone is of some importance as bearing upon differentiation. In the anthropoids, the relative shortness and horizontal direction of the occipital bone is very striking—especially is this true of the basilar process. In the degenerate types of human crania, or, at least, in the atavistic types, there seems to be a direct relation between the length and angle of the basilar process and intelligence. Dr. Clevenger called attention to the angle of the medulla as bearing upon intelligence, years ago, but Dr. Lydston's observations, although confirmatory of those of Clevenger, were made independently, as he had not had access to the work of the latter.

Horizontal index.	59.9
Circumference.	48.4 c.
Anterior demi-circumference	21.3 c.
Posterior demi-circumference	26.9 c.
Bizygomatic diam.	13.3 c.
Longitudinal diam.	196.5 mm.
Transverse diam.	122 mm.
Vertical diam. (vertex to foramen magnum)..	132 mm.
Occipito-mental diam.	241.5 mm.
Bifrontal diam.	95 mm.
Bimastoid diam.	114 mm.
Over vertex, from ear to ear	317 mm.
Ant. bord. foramen mag. to sup. occip. angle.	103 mm.

Fig. 14.

The excessive development of the jaws and alveolar processes in this specimen is such as is generally observed in the negro races, in whom the jaws are generally well developed and rarely

Fig. 15.—Skull of Mongolian suicide (Brachy-cephalic).

deformed. The only noticeable feature of this particular specimen is a high palatal vault.

The next specimen is not especially noteworthy from the standpoint of degeneracy, being interesting chiefly on account of its peculiar history, and its exceedingly fine development. It is, however, an excellent illustration of the brachy-cephalic cranial type.

The subject was a Chinese cigar-maker, of Chicago, who is remembered to have been thoroughly civilized and quite prosperous. Physically he was a fine, well developed and handsome fellow. He became engaged to a white girl, whose Mongolian affinity weakened at the last

moment, and this preying upon his mind, impelled our Mongolian friend to shoot himself. This was noteworthy, as he was the first Chinaman in America to commit suicide, and there has been but one since, as far as we can learn. The peculiar religious belief of the Chinese explains the rarity of suicide among those in America.

The contrast between the negro skull, Fig. 12 and Fig. 16, is very striking and obvious to the most careless observer. A front view of this specimen shows a splendid development of the jaws and teeth. We have never seen a finer or

Fig. 16.—Skull of Mongolian suicide (Brachy-cephalic).

more regular set of teeth than this. Like the negro race, the Chinese is characterized, on the average, by well formed and strong jaws and teeth.

Figure 17.—Negro panel-worker (Dolicho-cephalic).

The characteristically excessive development of the facial and jaw bones among the Chinese is well shown by a lateral view of this skull. The disproportionate development of the face and jaws in this instance is, however, much above the average Mongolian skull. By comparing the two views, the brachy-cephalic type of the cranium is readily observed. By comparing the views of this cranium with those of the negro shown in Figs. 12 and 13, one may observe the wide difference between the extreme types of high and low cranial indices. This is nowhere better

shown than by a comparison of marked Ethiopian and Mongolian types.

On examination of the crania of more degenerate types among the Chinese, it will be found that the tendency is towards a high cranial index. The tendency of the degenerate type of a brachy-cephalic race to become more brachy-cephalic, and that of a dolicho-cephalic race to become more dolicho-cephalic, is peculiar, but is borne out as far as our opportunities for study have permitted us to observe.

Aside from a change in the cranial index there are seen, among negroes particularly, many pe-

Fig. 18.—Negro panel-worker (Dolicho-cephalic).

culiar aberrations of form, one of which is shown in Fig. 28. The palatal arch in this Mongolian specimen is high, and the alveolar processes excessively developed. The measurements of this skull are:

Horizontal index	83.9
Circumference	50.6 c.
Anterior demi-circumference	29.4 c.
Posterior demi circumference	21.2 c.
Longitudinal diam.	174 mm.
Transverse diam.	146 mm.
Vertical diam.	145 mm.
Bimastoid diam.	127 mm.
Bifrontal diam.	96 mm.
Foramen magnum to superior occipital angle.	139 m.

The next specimen presents some extraordinary features. It is the skull of a celebrated negro panel worker, confidence operator and desperado who, at the time of his death, was the consort of a notorious courtesan who flourished in Chicago some years ago. This individual, after some years' dalliance with the law without especial harm to himself, was finally knifed in a brawl. A front view of the cranium shows the ordinary and characteristic negro facial type, with the exception, perhaps, that the bones are exceptionally massive and well developed. Unfortunately, the inferior maxilla is absent, a fact which we greatly deplore, as the general cranial development suggests to us the probability that the missing part presented some very interesting features for consideration. A lateral view of

this cranium shows the ordinary dolicho cephalic negro type. The cranial index is low, being 72.1. A comparison with Fig. 12, however, shows the extreme degeneracy of type in the latter to great advantage.

A view of this skull (Fig. 18), after a section of the calvarium has been removed, shows its most interesting feature. Skulls of such extreme thickness, even among negroes, are rarely met with. The consistency of the bone in this cranium is very dense and hard, and traditionally

Fig. 19.—Skull of prostitute (Dolicho-cephalic).

this negro, when he was alive, was noted for his butting propensities. Violent contact with such a skull would be apt to damage the fist of a Sullivan. Indeed, it is said that this fellow rather enjoyed the impact of a policeman's club.

We will state at this point, that we are of the opinion that the massiveness of bony development in this case is not due to disease. The

Fig. 20.—Skull of prostitute (Dolicho-cephalic).

general character of the overgrowth and the consistency of the bone would seem to support this view. Syphilis may produce thickening of the cranial bones, as some of Virchow's specimens show, but syphilitic bone does not present the characters and uniformity present in this case.

At the densest part of the calvarium this specimen measured 13 mm. in thickness, its average thickness being 11 mm. A comparison with Fig. 21 readily shows how phenomenal the osseous

development in this case is. The cranial measurements are:

Horizontal index	71.1
Circumference	47.8 c.
Anterior demi-circumference	25.4 c.
Posterior demi-circumference	22.4 c.
Longitudinal diam.	181.5 mm.
Transverse diam.	131 mm.
Vertical diam. (vertex to foramen magnum).	128 mm.
Bifrontal diam.	95 mm.
Bimastoid diam.	113 mm.
Bizygomatic diam.	126 mm.
Anterior border of foramen magnum to sup. occipital angle	117 mm.

The upper jaw and alveolar process in this skull is well developed, the only peculiarity being a low palatal vault.

Figs. 19 and 20 show the skull of a once notorious member of the Chicago *demi-monde*. She was a very tall woman of mixed Indian and white blood. The cephalic index shows what might be inferred from the appearance of the cuts—a decidedly dolicho-cephalic type and a peculiar outline. This specimen is the most symmetri-

Fig. 21.—Skull of prostitute (Dolicho-cephalic) Calvarium partially removed.

cally developed of the series, with the exception of the Sioux squaw, next to be described, and whether co incidental or not, the fact remains that this subject presented a higher type of intellectuality while living than any of the other subjects embraced in this essay. The skull is, nevertheless, of a degenerate type, as shown by its extreme tenuity and its markedly dolicho-cephalic index.

Fig. 21 shows the extreme thinness of the calvarium, which was at the point of section only 3 mm. in thickness. A striking feature of this skull is its freedom from prominences, its surface being uniformly smooth and rounded. In this respect the specimen differs greatly from another cranium of a prostitute in the same series which we have examined, but of which, unfortunately, we have no illustrations. In this case there was an excessive development of the occipital bone, the enlargement being symmetrical and most marked upon the left of the median line. The

right parietal eminence was excessively and disproportionately developed. The cranial index was markedly dolichocephalic.

The principal measurements of the skull at present under consideration are:

Horizontal index	67.09
Circumference	51.2 c.
Anterior demi-circumference	22.9 c.
Posterior demi-circumference	27.3 c.
Longitudinal diam.	190 mm.
Transverse diam.	130.5 mm.
Vertical diam.	128 mm.
Bifrontal diam.	88.5 mm.
Bimastoid diam.	71 mm.
Bizygomatic diam.	130 mm.
Anterior border foramen magnum to ant. sup. occipital angle	116 mm.

Fig. 22.—Skull of Sioux squaw (Dolicho-cephalic).

The jaw in the case is poorly developed but fairly well formed. In regard to the extreme tenuity of the skull, we do not believe that it is the result of pathological change. The general lightness of the bones and the symmetry of the skull are not consistent with the existence of such bone changes as might produce absorption

Fig. 23.—Skull of Sioux Squaw (Dolicho-cephalic).

and thinning. The markedly dolichocephalic type of this skull is interesting in view of the strain of Indian blood in the subject. As has already been observed, the degenerate type in dolichocephalic crania is in the direction of a still lower index and in this instance the admixture of Indian blood evidently determined the degenerative type. This observation would appear to be contradicted by the case outlined in Figs. 12, 13, 14. In this case, however, there

was an admixture of negro and Mexican blood, with a resultant degeneracy of form in general as well as in the cephalic index. This case, in fact, partakes in some respects of the character of a teratological rather than an atavistic type, *per se*—at least as far as the facial development is concerned.

A comparison of the prostitute's skull with the female Indian type next presented shows a marked difference in the cranial index, the disparity being 7.07. Even the negro in Fig. 17 is less dolichocephalic than this specimen. The

Fig. 24.—Half-breed Mexican and Negro (Ultra-brachy-cephalic).

next specimen, the cranium of a full-blood squaw of the Uncapapa Sioux, who was the wife of one of the leading malcontents in the recent Indian

Fig. 27.—Half-breed Mexican and Negro (Ultra-brachy-cephalic).

outbreak, and consequently of the better type of Indian development.

This specimen is exceptionally symmetrical and moderately dolichocephalic. Aside from the purposes of contrast, there is little of interest to be said of it in connection with the present series. The subject was as intelligent as the better class of her people average and there is nothing to be said regarding her from the moral

standpoint. Indeed, as the saying goes, the shoe might be on the other foot, as the Indian estimate of the Caucasian grave-robber is not a high one, as evidenced by his treatment of the desecrator of the Indian burial-places when the latter happens to be caught. However, as our connection with the aforesaid desecration is very remote, we trust that our red brother will extend his forgiveness.

Fig. 23 shows the same skull in lateral view. Its symmetrical outline is quite evident. The measurements are as follows:

Horizontal index	74.16.
Circumferential	51.2 c.
Anterior demi-circumference	26.6 c.
Posterior demi-circumference	23.8 c.
Longitudinal diam.	161 mm.
Transverse diam.	152 mm.
Vertical diam.	140 mm.
Over vertex from ear to ear	318 mm.
Occipital protub. to root of nose.	293 mm.
Bimastoid diam.	121.5 mm.
Bifrontal diam.	96 mm.
Anterior border foramen magnum to superior occipital angle	130 mm.

Fig. 26.—Outlines of ancient Peruvian skull mechanically deformed.

The superior maxilla presents arrested development. The vault is of medium height and the alveolar processes well developed. It will be found that in the Indian, as in all primitive races, a well-formed palate and regular teeth are the rule. It would be interesting, at some future time, to study the effects of civilization of the Indian in this regard.

The rule regarding the development of the jaws in the primitive races, has had especial stress laid upon it by Dr. Talbot in his work on irregularities of the teeth and jaws.³

The next cranium which we describe is the

³ I am of the opinion that the exceptions to this rule are much more numerous than Dr. Talbot would have us believe. Comparative studies of primitive crania and jaws show some very interesting facts. Among the older Egyptians, relatively small, oblique, narrow and pointed jaws, associated with relatively large and symmetrical cranial development were not infrequent. Arrested or excessive development of the facial bones was not rare. Among the skulls of the older Romans, skulls with peculiar obliquity of the occipital plane and angular outline of the occipital parietal regions are to be found. It is also highly probable that maxillary aberrations were not infrequent.

Specimens of Polynesian skulls show numerous examples of excessive and defective maxillary development. In as primitive a

most remarkable of the series and in many respects presents phenomenal characters.

The subject was a half breed Mexican and negro, who had left Mexico—his native country—for the good of his compatriots. While he had never distinguished himself by any startling act of criminality and had managed to keep himself out of the clutches of the law, he was identified with the petty criminal class which forms a prominent portion of all social systems, and with which Mexico is especially infested. He finally died in a public hospital, as a result of some acute disease with cerebral complications. The

Fig. 27.—Inferior surface of half-breed cranium.

general physique of this man was very fair, although he presented a generally overgrown and loose-jointed appearance. When alive he was a very peculiar looking specimen indeed, the

type as the Malay, excessive development of the inferior maxilla, with resulting extreme prognathism, arrested development of the superior maxilla and excessively high vault may be met with.

Among the mound-builders aberrations of cranial and maxillary development were frequent. Posterior flattening is frequent but not typical. Extreme oxycephaly and platycephaly are to be found in certain of these skulls. Arrested and excessive development of the jaws is often met with.

The Esquimaux type of jaw is varied by excessive breadth, great narrowing and marked obliquity on the one hand, or angularity on the other. A peculiar aberration occasionally seen is a flaring out of the lower border of the ramus. This is usually associated either with the broad and angular type. The result is a most striking "jowl."

Specimens of Aleut and Alaskan skulls also present aberrations of maxillary type.

Among the American Indians similar aberrations are to be seen. The Modocs, now almost extinct, showed pronounced variations of cranial and maxillary development; the teeth, however, were usually strong and well formed, as is typical of our native races. The crania of the native Californians of the lower types, the probable progenitors of the Piutes, Shoshones and Diggers, present marked and frequent cranial aberrations, associated often with excessive or defective maxillary development. Prognathism is frequent. The most typical maxillary characters of this degraded race are extreme obliquity and slightly marked angles of the inferior maxilla; so pronounced is this feature that the jaw is almost symmetrically curved. This type of jaw is interesting as bearing upon the theory of the relation of jaw conformation to character; the California Indians of the lower grades are the most degraded specimens of humanity imaginable. Ethnologists give the bushman a low mark enough in this respect, but he must yield the palm to the American Digger.

The Sioux present great variation of type of cranial and maxillary development. The great variation of orbital indices is striking and lends color to the suspicion that the importance of the orbital index as a criterion of race is a bit overdrawn.

Independently of mechanical causes there appears to have been great variation of type among the older Peruvians. Superior and posterior flattening and enormous development of the parietal eminences were frequent.

These aberrations tend to limit the application of the rule which Dr. Talbot has advanced regarding the pure races.—G. F. LYDSTON.

dome-shaped appearance of his cranium being exaggerated by a luxuriant crop of kinky wool, several inches in length, that stood straight out from his head. From a mental standpoint he was up to the average of the negro race, but morally speaking he was decidedly degenerate. One of his prominent characteristics was a very irritable and irascible temper.

This cranium, as is well shown in the appended illustrations, is most markedly brachycephalic; indeed, its circumferential outline is almost perfectly round, its longitudinal and transverse diameters being nearly equal. The term dome-shaped is as nearly accurate as possible from a descriptive standpoint. It is a singular fact that the degenerate type of the African skull often presents the oxycephalic or rafter-headed type, even when the dolichocephalous index is pronounced. These rafter heads are often seen.

Fig. 28.—Dome-shaped cranium; Mulatto (Brachycephalic).

The skull at present under consideration is, as already remarked, a distinctive dome shape, which corresponds not at all with the rafter head.

The peculiar conformation in this case is evidently not the result of pathological conditions or mechanical pressure. The vault of the cranium is quite symmetrically developed, although the base of the skull is decidedly asymmetrical, as will shortly be shown. We know of no mechanical means which might have caused the peculiar dome-like form of this specimen, and we have been unable to find mechanically deformed crania of a similar type. Such deformities as those presented by the Chinook or Flat-head Indians are quite familiar types of skulls mechanically deformed. Certain specimens found in ancient Peruvian graves are almost precisely identical with the characteristic Chinook type and

show a probably common origin of the two races. This type is fairly well shown by the conventional outline of Fig. 26.

There are several interesting features in connection with the skull under consideration: One of the most striking is the extreme shallowness of the orbits. This is well shown by comparison with some of the other types already described, the measurements being one and three quarters inches from the upper margin of the orbit to the optic foramen, while in the Indian and negro skulls in this series the orbits measure two inches in depth. The outer walls of the orbits encroach upon the cavities, giving a still more marked appearance of shallowness. The form and index of the orbit is given considerable weight by anthropologists as a criterion of racial type.⁴

The inferior maxilla also presents some pecu-

Fig. 29.—Dome-shaped cranium; Mulatto (Brachycephalic).

liarities: The coronoid processes are very small and short, the body long and the angles very oblique. The anterior alveolar process is excessively developed. The same is true of the alveolar process of the superior maxilla, it being so situated on the outer surface of the jaw that the teeth were necessarily tipped in to facilitate occlusion with the lower teeth. The central incisors were evidently lost in early life, the alveolus being absorbed and the border of the jaw only one-eighth of an inch in thickness at this point. The palatal vault is very low and the general development of the jaws imperfect.

⁴ I claim, and have verified by comparative studies of orbita development, that the form of the orbit is of even greater importance as bearing upon the question of degeneracy of type. The marked variation of the form and measurements of the orbit is incidental to differentiation, is seen by observation of the anthropoids. There is a striking difference between the members of the Simian group in this respect, and a still greater difference is noticeable between the *simiidae* and *lemnidae*. The shallowness and obliquity of the orbits in Fig. 24 is strikingly similar to the characters observed in the gorilla and chimpanzee, which are quite different from those noted in the orang. The general outline of the orbits and their proportionate relation to the facial development in Fig. 12 are also decidedly Simian in character.—G. F. LYDSTON.

There is a marked deflection of the vomer and ossæ nasi, evidently of non traumatic origin and due to excessive development of the osseous and cartilaginous structures of the septum nasi. The nasal spine is enormously developed. The cranial index in this case is extraordinarily high, being slightly above the maximum given by most anthropologists. The type is as marked in the direction of a brachy-cephalic index as is Fig. 13 in the direction of a low or dolicho-cephalous index.

Fig. 27 shows the inferior surface of the skull under consideration. A glance suffices to show

Fig. 30.—Skull of Western desperado (Brachy cephalic).

its remarkable asymmetry. The foramen magnum is almost entirely to the left of the median line. A line drawn through the center of the foramen traverses the median line of this surface at an angle of about forty-five degrees. The center of the anterior border of the foramen is situated at 76.5 mm. from the left and 58 mm.

Fig. 31.—Skull of Western desperado (Brachy-cephalic).

from the right mastoid. The center of the posterior border of the foramen is 64 mm. and 61 mm. from the left and right mastoids respectively. The margin of the foramen is extremely thin and the occipital ridges very prominent. The measurements are:

Horizontal index	98.1
Circumference	46.5 c.
Anterior demi-circumference	22.6 c.
Posterior demi-circumference	23.9 c.
Longitudinal diam	146 mm.
Transverse diam	143 mm.
Vertical diam	148.5 mm.

Root of nose to occipital protuberance . . .	313 mm.
Anterior border foramen mag.to sup.occ.angle, 91	mm.
Bimastoid diam.	115 mm.
Occipito-mental diam	248.5 mm.
Bifrontal diam.	95 mm.
Bizygomatic diam.	133.5 mm.
Over vertex from ear to ear	350 mm.

On comparing the longitudinal, vertical and transverse diameters of this remarkable skull with those of some of the others of the series, the relatively great height of this dome-like cranium

Fig. 32.—Skull of Western desperado (Brachy-cephalic)

is made very apparent. Thus the diameters are:

	Trans.	Long.	Vert.
Fig. 12	122 mm.	196.5 mm.	132 mm.
Fig. 15	146 mm.	174 mm.	145 mm.
Fig. 17	131 mm.	181 mm.	128 mm.
Fig. 19	130.5 mm.	190 mm.	128 mm.
Fig. 21	152 mm.	161 mm.	140 mm.
Fig. 31	140.5 mm.	180 mm.	136.5 mm.
Fig. 33	149 mm.	168 mm.	118 mm.

Fig. 33.—Desperado and train-wrecker (extreme Brachy-cephalic).

Those of the specimens under consideration being trans., 143 mm., long., 146 mm., and vertical 148.5 mm., a comparison with Fig. 33 is especially interesting.

While making some observations at the Joliet penitentiary we discovered an example of the dome-shaped brachy-cephalic cranium, which strongly resembles the extraordinary specimen just described.

This subject is a mulatto about twenty-three

years of age, who is doing time for attempted murder. He is a surly, truculent fellow, of a low grade of intelligence and inclined to be unruly. He is at present suffering from a mild type of syphilis. The form of the cranium is well worthy of remark, the more especially as it so nearly approximates the types shown in Figs. 24 and 25.

The facial bones, jaws and teeth in this case were extremely well developed and the palatal vault normal. There was no history of mechanical compression, and as the subject was born in Tennessee such a cause is improbable, if not impossible.

The measurements were not complete. As far as taken they were:

Horizontal index	76.7
Root of nose to occ. protuberance over vertex.	39.5 c.
Circumference	50.8 c.
Transverse diam	145 mm.
Longitudinal diam	191 mm.
Occipito-frontal diam	59 mm.
Occipito mental diam	28.5 mm.

The dome like form of this cranium will be more evident on comparison of the two principal

Fig. 34.—Desperado and train-wrecker (Brachy-cephalic).

measurements with those of a skull of average development. A comparison was made with that of one of the white orderlies in the prison hospital, a man of fine physique and good cranial development. It was found that while the measurement over the vertex was the same as that of the negro, 39.5 c., the circumferential measurement was 58.5 c.

The next specimen (Fig. 30), is the skull of a noted Western criminal and desperado, who was lynched for train wrecking in Wyoming a number of years ago. The conduct of this man during the progress of the lynching stamped him as a bravo of the most hardened type. An attempt was made to induce him to relate the particulars of a murder in which he had participated, the wife of the murdered man being present at the hanging and anxious to learn the details of her husband's death. To the persuasive efforts of the "regulators" and the tears and entreaties of the widow of his victim, he replied: "D—n it, you'll hang me if I tell, and you'll hang me if I

don't. So here goes," saying which he deliberately kicked the barrel upon which he was standing out from under himself, and thus saved his self-appointed executioners all further trouble.

This specimen is brachy-cephalic and chiefly characterized by its marked asymmetry.

The occipital region in this cranium is excessively developed, prominent and bulging, being especially prominent on the left of the median line; the occipital protuberance is situated about 8 mm. to the left; the parietal eminences are very asymmetrical, the right being very prominent and of irregular contour; the palatal vault is of medium height, the teeth regular and the maxilla well developed; the measurements are:

Horizontal index	77.8
Circumference	50.3 c.
Posterior demi circumference	28.6 c.
Transverse diam	140.5 mm.
Anterior demi-circumference	21.9 c.
Longitudinal diam	180 mm.
Bifrontal diam	105 mm.
Bimastoid diam	126 mm.
Bizygomatic diam	134 mm.
Root of nose to occipital protuberance	312 mm.
Over vertex between auditory meati	327.5 mm.
Foramen magnum to sup. occipital angle	128 mm.

Fig. 35.—Skull of Western Desperado (Brachy-cephalic).

Viewed from above (Fig. 32), this cranium shows a fairly symmetrical outline. The above illustration is used for the purpose of comparison with Fig. 35.

The next specimen is by far the most interesting of the series from the standard of degeneracy, and is certainly the most markedly asymmetrical. If it were possible to conceive of a special criminal type of cranium, this would, in many respects, be an ideal illustration. The subject was a noted Western desperado and train-wrecker, who was lynched at Carbon, Wyoming, back in the seventies, for an attempt to wreck a train at Medicine Bow. In this attempt he was assisted by the individual represented in Figs. 30, 31, 32.

The extremely disproportionate breadth of this cranium is well shown by the above illustration. The meagre development of the frontal region is

very noticeable. On viewing this skull from above, the peculiar twisted appearance which may be observed in connection with the cranial type of the criminal in general will be observed. The orbits are relatively large, and the face, as a whole, of a decidedly "squatty" appearance. The absence of the inferior maxilla is to be regretted, although, considering the vicissitudes which the skull has experienced, its otherwise perfect state of preservation is rather remarkable. After the lynching of this gentleman, the body was buried in a hastily improvised and shallow grave, from which it was very promptly resurrected by those scavengers of the prairie, the coyotes. The skull was finally found by a railroad employé, and subsequently used as a paper-weight for some years.

Judging from the conformation of the cranial and facial bones, the lower maxilla, while probably well, or perhaps excessively developed, was without doubt asymmetrical. The relatively defective frontal development of this skull is its most striking feature when viewed in its anterior outline, and is best shown by comparison with Figs. 12, 13 and 17. In the former the extreme breadth is 122 mm. and the extreme length 196.5 mm., while the frontal breadth is 95 mm. In the skull under consideration, however, although the extreme breadth is 149 mm. and the extreme length but 171 mm., the frontal breadth is only 90 mm. The great disproportion in the measurements is at once obvious. In Fig. 17 the greatest breadth is 131 mm. and the greatest length 181.5 mm., yet the transverse frontal diameter is 95 mm.

The disproportion is not compensated for in Fig. 33 by an increased longitudinal development of the frontal bone.

The twisted appearance of this skull is most evident on comparison of the parietal eminences. These are very prominent on both sides, the left being much the larger of the two; the occipital region is greatly deformed and exceptionally prominent, the bulging being most marked upon the left of the median line. The asymmetry of development is shown by a comparative measurement of the distance of each parietal eminence from the occipital protuberance; this measures on the right side 132 mm. and on the left only 119 mm. The squatty, animal-like type of this cranium is shown by a comparison of its vertical measurement with some of the others of the series; from the highest point at the vertex to the anterior border of the foramen magnum the measurement is 118 mm.; that of Fig. 13, which is so distinctively anthropoid in its development and outline, the vertical measurement is 132 mm.; of Fig. 16, a symmetrical brachy-cephalic type, is 145 mm.; of Fig. 17, 128 mm.; of Fig. 21, 140 mm.; of Fig. 25, 148.5 mm., and of Fig. 31, 136.5 mm. A little study of these measurements

will show the extreme animality of type in this cranium, even as compared with others of a pronounced degeneracy of type.

A view from above (Fig. 35) shows the circumferential outline of this specimen. By comparing the quadrants of this illustration, the pronounced asymmetry of development is easily seen.

The superior maxilla in this skull is well developed, although the alveolar process shows an inferior development; the palatal arch is exceedingly low; the left superior maxilla is much smaller than the right; the palatal processes show great asymmetry, the right being 61 mm. and the left but 5 mm. in breadth. The measurements of this cranium are:

Horizontal index	87.13	
Circumference	49	c.
Anterior demi-circumference	20.35	c.
Posterior demi-circumference	28.65	c.
Longitudinal diam.	171	mm.
Transverse diam.	149	mm.
Vertical diam.	118	mm.
Bifrontal diam.	90	mm.
Bimastoid diam.	108.5	mm.
Bizygomatic diam.	132	mm.
Vertical circumference from ear to ear	279	mm.
Center of left parietal prominence to occipital protuberance	119	mm.
Center of right parietal prominence to occipital protuberance	132	mm.
Anterior border foramen magnum to superior occipital angle	128	mm.

ARE INEBRIATES CURABLE?

BY T. D. CROTHERS, M.D.,

SUPERINTENDENT WALNUT LODGE HOSPITAL, HARTFORD, CONN.

Any satisfactory or reliable answer to this question must come from a scientific study of the nature of drunkenness. Fortunately, recent advances of science have furnished many facts and data from which to determine this question, apart from personal opinions and theories.

A very curious chapter of psychological literature could be written on the popular theories of the day concerning drunkenness and its curability. Thus persons who believe inebriety to be a vice and sin, are confident that conversion will cure every one. Many so-called gospel temperance advocates claim to have cured thousands of inebriates, and assert with great emphasis that the grace of God through a change of heart will make sober men of all such persons in all conditions of life. Another class believe drunkenness to result from a weak will power, with absence of plan and purpose in life; the great remedy of which is the pledge. The old Washingtonian revival, the Father Matthew movement, and the blue and red ribbon revival wave, are illustrations of the practical application of this theory. The most wonderful success in the cures of drunkards is claimed by the adherents of this method of treatment.

Many persons proclaim that drunkenness is always due to a wilful criminal impulse, which can only be cured by punishment and suffering. They would have laws for more severe punishment, established the whipping-post, confine drunkards in dungeons in irons on bread and water, and finally use capital punishment. Curiously the believers of this theory cite examples of its practical value in the cure of many cases.

It is clear to many people that the prohibition of alcohol will cure drunkenness effectually. Others assert that drunkenness is a mere stomach trouble, and that specific drugs will destroy the appetite; also, that by treating this appetite to excess of spirits in everything used, a permanent repugnance can be created. A large number of cures are said to be made by these methods.

The drug specific treatment is now quite prominent, but as in many other matters, the results are subjects of faith rather than of demonstration.

These and other theories are proclaimed from the pulpit, platform, and even in the court room, and are scattered broadcast in journals, tracts, and books; and yet all competent authorities agree that drunkenness is increasing. Some reasons for this are apparent in the legal method of curing drunkenness. The fines and short imprisonment, supposed to stop all further use of spirits, produce the opposite effect, and intensify all the conditions which impel the drunkard to drink. Statistics show beyond doubt that the station houses and jails, are more dangerous and destructive than the saloons, that ninety-eight per cent. of all inebriates who are punished for the first time by fines and imprisonment, are re-arrested for the same offense continually until death. There is a grim irony in the method of cure, that makes recovery more and more impossible, and finally completely destroys the victim. Evidently as long as the drunkard is regarded from the moral side alone, and judged by the theories urged a thousand years ago in explanation of his condition, his curability will be doubtful and exceptional.

Another very curious chapter might be written on the spasmodic efforts, through parties, societies, and agitations, to rouse the public to use some curative measures for drunkenness. The literature of these movements is the strangest compound of errors and misconceptions, that are repeated without a question or doubt of their reality. Take the established facts concerning alcohol, they could all be put on a single page, and yet hundreds of volumes and pamphlets have been written on this topic, and these do not include all. A dozen different text books are published, to teach the action of alcohol to school children. Hence it is almost impossible, from any comparison of theory and practice, to form any conclusions as to the actual curability of drunkenness. The scientific student must begin

his inquiries without support from present knowledge, and aside from this mass of opinion and theory.

He must approach the subject entirely from the physical side, and seek to ascertain what drunkenness is, its causes and character, and why alcohol or other narcotics are used so excessively, and beyond all limits of reason and self-preservation. When these facts are understood, the question of curability can be answered. The scientific method to be pursued in this study, is the same as in all other physical problems. First, gather and tabulate the histories of a large number of inebriates, then make comparative studies of these records, and ascertain what facts, if any, are common to all of them. The history beginning with the individual, should extend back to his parents and grand-parents. Giving accurate details of all family diseases and accidents, and diseases which have appeared in different members of the family; also their habits of living, and occupation; their successes and failures in life; their character, conduct, surroundings and longevity. To this add the history of the collateral branches and near relatives up to the present. Then coming to the individual, record all the facts of his birth, and the condition of his parents prior to his birth; his early childhood, diet, diseases, occupation and surroundings, and the culture and cure received. Also all the accidents, diseases, nerve, and muscles, strains, shocks and failures; his culture, surroundings, and all the facts of his life up to the onset of his drink history; the circumstances attending the first use of spirits, and the effects upon him, his habits and mode of living, together with all the circumstances of his life and diet, surroundings, and its failures and successes. The effects of alcohol and its influence over his daily life, and all the other facts of his history. While the accuracy of many of these facts may be difficult to secure, certain general principles will appear, which must have been followed or preceded by certain minor facts, either known or unknown. The more exhaustive these facts are, the more accurate the conclusions. From a grouping of a large number of such histories, a startling uniformity in the causation, development and termination appears. Literally the same causes, the same surroundings and conditions appear in nearly every case. To illustrate, heredity as a causation appears in over sixty per cent. of all inebriates. The parents and grand-parents have been continuous or excessive users of spirits, or have been insane or mentally defective, or have been consumptive, or had rheumatism, gout, or some other profound constitutional disease, before the birth of the child. These physical states have been transmitted, and burst into activity from exposure to some peculiar exciting cause. In twenty per cent. there will be

found the same history of disease and injury preceding the use of spirits. Thus, blows on the head, sunstrokes, railroad accidents, and injuries which have caused stupor or periods of unconsciousness, or profound wasting diseases, from which recovery has followed, and with it the use of spirits, which sooner or later developed into drunkenness. Mental shocks from grief and joy or other profound emotional strains, are followed by an intense craving and drunkenness. Ten per cent. will give a clear history of brain and nerve exhaustion, preceding the inebriety. In five per cent. bad sanitary surroundings, bad living and diet have been the exciting causes, and in a small percentage the causes are obscure and unknown. These are some of the most prominent facts appearing from a comparison of the histories of a large number of cases. Many of the causes are combined in one, such as heredity, bad surroundings, brain exhaustion, or brain injury. In some cases, old heredities appear in the second generation, or peculiar nerve injuries that develop into inebriety.

Another fact appears from these histories equally startling, viz.: The uniformity of the progress and march of each case. A certain progressive movement is noted along a uniform line of events, that can be anticipated and predicted. Halts, diversions and apparently retrograde movements may occur, but the large majority of all drunkards begin at a certain point, and march down the same road, and cross the same bridges, and arrive at the same termination. To find where the case started and where it is at present is to find accurate data from which to predict the future with much certainty.

Drunkenness often takes on the form of periodicity, in which the use of spirits occurs at distinct intervals. These drink storms, like epilepsy, are followed by a free interval of health and sobriety. During this free interval the victims display mental vigor and great resistance to all exciting causes, then suddenly relapse, and use spirits to excess for a fixed time and recover. Such cases exhibit a strange cycle like movement, coming and going at exact intervals that are uninfluenced by circumstances or conditions. Some are solitary midnight drinkers; others only drink at certain places and at certain times and seasons. Many curious and fascinating facts that are not understood, appear in the history of this class, and suggest a range of causes, yet to be studied.

Such are some of the general facts which are found to be uniformly present in most cases, and which indicate beyond question that drunkenness is a disease. The mental degeneration and obscure forms of physical disturbances, associated with a craving for spirits that dominates every consideration of life, point to a form of insanity, in which both the brain and nervous system

appear to suffer from paralysis and exhaustion. The use of spirits may cause the paralysis and favor the exhaustion which precedes from it. Intoxication exhibits in a concentrated form the common types of insanity, mania, melancholia and dementia, in a brief time. The injury from these states must be very great, and the inference that the demand for spirits is often a symptom and not the disease, is amply confirmed.

From these and many other facts the curability of drunkenness becomes a question of the application of scientific measures and means to conduct or assist the case back to health again. The condition to treat is that of progressive brain and nerve exhaustion, lowered vitality, with damaged and perverted functional activities. The removal of alcohol does not remove the disease, but only one exciting or predisposing cause. Jails isolate and prevent the drunkard from procuring spirits, but experience shows that forced abstinence alone always intensifies the drink impulse, and increases the incurable condition. Something more is required. Enthusiastic appeals to the emotional powers and will, are not curative, because the emotions and will are diseased; the higher moral faculties are perverted and cannot act normally. The drunkard has been switched off the main line of healthy life and living, upon the side-track of progressive dissolution, the opposite of evolution. The question is, what means and appliances can bring him back to the main life of health; can the will power, or prayer, or any specific drugs, or appeals, or threats do it? Are there any agents along the lines of the marvelous, or any miracles that will save the drunkards? The laws of dissolution are as fixed and certain as those of evolution, and the change from the one to the other must be along the line of physical laws and forces, that move without a shade or shadow of turning. The curability follows from the application of certain general principles, the first of which is the isolation and change of surroundings. The drunkard must go into a quarantine, where all the external conditions of life will antagonize his disorder and assist nature to return to health. In a quarantine station or special asylum, the diet, baths, exercise, medical study, and care, with all other means, can be applied with military exactness. Each special phase of disease and form of degeneration can be treated from its particular symptoms, with particular remedies. Nerve and brain rest, the restoration of all the organic and functional activities, can be obtained by means under the care of the medical man. Thus, the drink impulse is overcome and dies away with the increasing vigor of the mind and body. Like insanity, drunkenness is cured, not by drugs alone, but by building up the body, through all the avenues of nutrition, healthful exercise, regulated mental and physi-

cal surroundings, and appropriate drugs. Drunkenness must be recognized as a disease legally, and the victim forced into conditions where he can live along the best sanitary lines of health; where medical treatment and control can be exact and perfect, and where physiological and hygienic training in its broadest and best sense can be applied. The details of the application of these principles will suggest themselves to every one. These principles were suggested for the treatment of drunkenness nearly two thousand years ago, but only recently have they received any special attention. Thirty years ago the first pioneer asylum for the application of them was opened at Binghamton, New York. A furious wave of opposition eventually destroyed it, but the truth which it exemplified was above the superstition and prejudice of the hour. To-day there are over a hundred asylums and houses in the world for the treatment of drunkards from the physical side. Notwithstanding the storm of opposition which greets every new advance in science, and which in this case is not over yet, the success of the asylum treatment has opened a new pathway of great promise for the future. Public sentiment still denies the disease of the drunkard, and legislatures refuse to give legal power of control; and asylums for inebriates must go on as private enterprises, opposed by superstition, without appliances or experience, and treat only the most incurable cases, who come to them as a last resort, and from a forced necessity. The wonder is that any success should follow their crude efforts, and yet the statistics of the largest of these asylums indicate a degree of curability that could not have been anticipated. The first statistical study was made at Binghamton, in 1873. Inquiries were made of the friends of fifteen hundred patients, who had been treated five years before at the asylum. Of eleven hundred replies, sixty-one and a fraction per cent. were still temperate and well, after a period of five years. It was a reasonable inference, that if sixty-one per cent. were still restored after this interval, a large percentage would continue so through the remaining life. Another study of two thousand cases was made at Fort Hamilton, N. Y., which revealed the fact that thirty-eight per cent. of these cases remained temperate and sober, after an interval of from seven to ten years from the time of treatment. In the returns of three thousand cases studied at the Washingtonian Home at Boston, Mass., thirty-five per cent. of all the living persons who had been under treatment from eight to twelve years before, were temperate and well.

In many smaller asylums, both in this country and Europe, where the number studied were limited to a few hundred or less, and the interval or time since the treatment was from four to eight years, the number reported as free from all

use of spirits ranged from thirty-two to forty-one per cent. While these statistical facts are not to be considered as final and conclusive, because they do not extend over a sufficient length of time from the period of treatment, or include a large number of cases, they are full of hopeful possibilities, and indications that cannot be ignored. In view of the fact that many of the asylum cases are largely incurable, and since the faults and imperfections in both the building and management of asylums are unavoidable at present, the curability of drunkenness by this means is more certain than in any other way. The same principle obtains as in insanity—the more recent the case, the more curable; the more complete and thorough the appliances, the greater certainty of cure. These estimates of cure are sustained by all accurate observers, in both Europe and this country, and have become the starting point for most enthusiastic work by many pioneers.

It is a reasonable inference that if one in every three can be cured by the present imperfect methods, a much larger proportion will be restored to health by the improvements and better institutions of the future. It is evident that a large number of all criminals, insane idiots, and defectives come from the ranks of incurable drunkards. If such degenerate cases could only be housed and kept under sanitary control, a visible lessening of these defects would follow. Many other facts sustain the opinion that all drunkards, both recent and chronic, should come under legal control and be put in quarantine asylums, until cured, or be retained for a lifetime. The practical workings of such asylums are assured in many ways, as well as the fact of the curability of a large number of cases, that are literally made worse by the present blundering efforts to improve them. These scientific methods of curing drunkards may be summarized as follows: First, legislate for their legal control, then organize industrial hospitals in the vicinity of all large towns and cities. Tax the spirit traffic to build and maintain such places, just as all corporations are made responsible for all the accidents and evils which grow out of them. Arrest and commit all drunkards to such hospitals for an indefinite time, depending on the resoration of the patients; also commit all persons who use spirits to excess and imperil their own and the lives of others. Put them under exact military, medical, and hygienic care, where all the conditions and circumstances of life and living can be regulated and controlled. Make them self-supporting as far as it is possible, and let this treatment be continued for years if necessary. The recent cases will become cured and the incurable will be protected from themselves and others, and made both useful and self-supporting. Who can fully estimate the benefits to society, to morals, and to civilization, by prompt-

ly isolating such persons and keeping them in normal states of living? Who can estimate the relief to the taxpayer by the removal of the perils to both property and life from drunkenness? This is not a theory, but a reality, only awaiting practical demonstration, when the superstitious opposition of public opinion dies away. The time has come to look at this problem in its true light.

The curability of the inebriate is far more certain than that of the insane. The liberty of both is equally dangerous; one is recognized, the other is seldom restrained until he becomes a criminal. The moment a man becomes a drunkard he forfeits all rights to liberty and becomes a ward of the State, and should be controlled by it. It is dense ignorance that permits any one to destroy his life and property by drink on the supposition that he is a free moral agent. The inebriate is mentally and physically sick, and needs the same help as the insane, and the question of care is simply one of adequate means and remedies to reach the disease. The few pioneers working along these frontier lines of research, looking beyond the dust and conflict of temperance agitation, are fully confident that not far in the future the drunkard will be recognized and cured; and the mysteries of the great drink problem will disappear before the march of scientific truth.

STRICTURE OF THE URETHRA. ITS CURE BY PAINLESS DILATATION AND BY ELECTROLYSIS.

BY GEO. H. SIMMONS, L.M., M.D.,
OF LINCOLN, NEBRASKA.

There are five ways of curing stricture of the urethra, viz.: by divulsion, external urethrotomy, internal or dilating urethrotomy, simple dilatation, and electrolysis. The first named is dangerous, inexact, rude and unsurgical, and is now practically relegated to the dark ages in the history of urethral surgery.

External urethrotomy is associated with more or less danger, but it is an operation that has to be resorted to in many cases.

Dilating urethrotomy has many ardent advocates, and while much can be said in its favor much can be said against it.

In this article, however, I propose to speak principally of the method by dilatation and that of electrolysis, calling attention to the plan I have adopted in dilating with my gleet olives.

I have been in the habit for some years of using Van Buren's steel sound, and it always impressed me that there was a good deal more pain associated with the passing of them than was necessary, considering what was required. The

average patient who comes to the surgeon for relief of stricture, will probably have only one. A few may have several, but the large majority will have but one or two. Such being the fact, what is the use of subjecting the patient to the pain of dilating the whole urethral tract, when the necessity exists only in a very small portion of it. The most severe pain is often felt, and continuously too, at the meatus, where there is no necessity for dilating or cutting, unless it be to admit the sound. And yet this continued stretching is kept up, and the pain associated therewith, from the time the sound enters the urethra until its withdrawal.

Dr. Fessenden N. Otis defines stricture of the urethra as "An abnormal contraction of the urethral calibre at some point at or *between the meatus urinarius and the bulbo membranous junction.*" The same author says that of 258 strictures which he located only 14 extended farther than $5\frac{1}{4}$ inches from the meatus, and only six beyond $6\frac{1}{4}$ inches. Why then is it necessary to use a sound 8 inches to a foot long, extending in many instances several inches beyond the stricture. After the instrument has passed through the meatus, there is usually but little pain until the prostatic portion is reached, then severe pain is felt and considerable reflex disturbance is liable to take place; and both are augmented on entering the bladder. Urethral fever and other troubles are liable to follow when the bladder is entered, or if the sound is pushed beyond the sinus pularis containing the orifices of the ejaculatory ducts. I have frequently had patients faint when the long sound is passed first, but this would not occur if it were not pushed through the prostatic portion. Epididymitis, with all its *acute* suffering, and *permanent* injury—probably taking away the procreative powers if both testicles should be affected—is a thing to be decidedly feared. And yet every time the sound is passed beyond the triangular ligament we may look for such occurrence, but not otherwise. For these reasons I have discarded the use of the Van Buren sounds and use my gleet olives. The first time I used them was two years ago, on a young man who came into my office, and asked me if I could cure him of stricture, and let him go home in three hours. He was from Kansas, having come to Lincoln on other business, and had to return immediately. I made no notes of the case at the time, so do not remember what history he gave. I examined him and found a stricture back through which a 15 (French) bougie à boulé would barely pass. I suggested cutting with an Otis urethrotome, but he would not listen to it. I did not dare to use electricity long enough to cure at one séance, so concluded to use my gleet olives, which I will describe farther on. I knew it would be impossible to do anything with the ordinary steel

sound, for to break down the stricture with them would be to inflame the whole urethral tract so much, that were it possible it would be dangerous.

In its flabby condition the penis measured a little over three inches, so according to Otis' rule it should take a No. 31 or 32 sound. Having thoroughly cocaineized the urethra at and anterior to the stricture, I kept the parts deadened so that no pain was felt during the whole operation except when the larger olives were passing the meatus, which had to be cut before No. 27 would pass. I commenced with No. 17, and forcing it through the stricture immediately pulled it back and so kept moving backward and forward until it would pass easily. I then took No. 20 and followed the same plan, then 22 and then 26. Attempting 27 found that I could not pass the meatus. Having cut this, passed 27, 29, 30 and 32. A little hæmorrhage took place but not much. With much care the instruments were made absolutely aseptic. After the operation I inserted a urethral suppository of iodoform, also gave him some to use at home. The operation lasted barely half an hour, after which the patient rested for two hours in the recumbent position.

When he left he promised to write in a week and later, but I heard no more of him. I was quite anxious about the case and imagined all kinds of terrible things for a while, but finally forgot all about him, until one day five months after operation he came into the office.

He said he had considerable pain for about a week, but in ten days it had all left and he had had no trouble since. Passing No. 30 olive I could find no indication of stricture. The cure was perfect. I have never attempted to cure as bad a stricture, as far as calibre is concerned, at one sitting since, but would not hesitate if necessity required. Since then I have treated several cases with this method, only taking more time, and with success in each case.

The gleet olives referred to were made for me for the cure of gleet with electrolysis, and while I use them in the place of ordinary steel sounds for dilating stricture, and for which purpose I have had them slightly altered, still that was not the idea when I first had them made. They are simply long olives, the smallest No. 17, (French) and three-fourths of an inch long, increasing with gradual gradation to No. 35. Both ends are cone shaped. They screw on to a stiff handle for dilating purposes, or a flexible insulated handle for electrical work. These handles are about nine inches long and can be marked off into quarter inch spaces, for measuring distance of stricture from meatus.

I commenced using galvanism for gleet as a *dernier ressort* in a case of intractable gleet that had been the rounds of the profession in Cincin-

nati before coming west. His history was as follows: Aged 33, stout, phlegmatic, such a character as usually worries but little, but this disease did worry him. Had gonorrhœa four years previous, which was cured in about two months. Some nine or ten months afterwards he contracted another dose, and while the acute symptoms soon subsided it left him with a gleet discharge which continued in spite of everything that had been done. He had been under two or three good men in Cincinnati but without relief. He had been examined for stricture several times, but none had been discovered, and I failed to discover any sign of a contraction. I tried various methods to cure him but all failed. I was then, as now, using galvanism for endometritis, and with success in most cases, stopping the discharge. I determined to try it for this case, so had an electrode made about an inch and a half long and No. 28 French scale—the normal calibre of his urethra.

Having thoroughly cleaned the urethra with retrojection of solution of peroxide of hydrogen, I inserted the electrode, attached to the negative pole of the battery down about to the bulbo-membranous portion. A sponge attached to the positive pole was held over the thigh. I turned on the current till he could just feel it, about three milliamperes, and gradually withdrew it, taking between eight and ten minutes to do so.

There was considerable pain afterwards during micturition, but after three days this had all disappeared. There was, however, no change in discharge. On the fourth day I repeated the séance, taking about eight minutes. This too was followed with pain on micturition, but not as severe, nor did it last quite as long. There was lessening of the discharge, but not to a very great extent. Three days after I gave another treatment, and after this some pain, but less severe and quite an appreciable diminution of the discharge. I gave altogether 17 treatments varying from two to five days apart, using from two to seven milliamperes, never enough to cause pain. The discharge gradually decreased after the second treatment, and he was discharged as cured nine weeks after commencing the electrical treatment. He remained here six months afterwards, during which time he had no sign of return of the trouble.

During the time the above case was under treatment, a young man about 30 years of age consulted me for gleet. He was in great agony of mind, for he was engaged to be married in October, and this was April. In the July previous, nine months before consulting me, he contracted the clap, and had had a discharge ever since. On examination I found two strictures of large calibre, one and a half and three inches back. He was willing to have them cut, so I cut them with Otis' urethrotome. No trouble resulted except a

little urethral fever. I used my gleet olives for dilating, to keep the strictures from reforming. I waited two months for the discharge to stop, using antiseptic injections, etc., but there was no diminution in the discharge. And the month of October was coming on apace. I advised him to postpone the important event if he could possibly give an excuse, but he said he had none. Having the good results in the case I was treating with the galvanic current, I determined to try it on him. At first the result was discouraging. The discharge did not decrease, but on the contrary increased and set up a more or less inflammation, so that for nearly ten days micturition was very painful. I kept up the treatment, however, every three days, using mild current; after ten days the pain gradually left and at the end of two weeks the discharge stopped almost suddenly. I kept up the treatment about ten days, then stopped, thinking I had cured my patient in two weeks. But I was doomed to disappointment, for in about a week the poor fellow came back blue as ever. The discharge had started on him again but it was slight. I commenced the treatment and after one séance the discharge stopped. But I gave a treatment twice a week for four weeks more, then stopped, as I believed him cured. Six weeks afterward he came in to report that he was going East to get married and settle down there. He thought himself entirely cured, but promised to write if he had any trouble. I have never heard from him, so believe him cured.

Since then I have used galvanism in five cases of gleet. Three of which resulted in a cure. In one after four weeks treatment—two treatments a week—no result could be noticed, and the patient suddenly stopped coming, and I have not seen or heard anything of him since. In the other there seemed to be unusual pain after each treatment, and after three trials the patient would not have it tried again. I have since practically cured him with injections of peroxide of hydrogen and solution of boracic acid.

In reference to the cure of stricture by electrolysis, I have had so little experience compared with others who have written upon the subject that it would be presuming a good deal if I should attempt to take sides against the opposers of Newman and his followers. In more than one case the discussion has gone so far that if the lie was not given it came so near to it that a shadow of a doubt would be felt in the mind of the reader as to whether it was so meant or not.

So without wishing to take part in the discussion, I would say that I have cured five cases of stricture with electrolysis and failed in one. Three of these cases were accompanied with gleet discharge, which was cured in each case. At some future time I propose to elaborate more on my experience with electricity, especially in

urethral diseases and in impotency, but before doing so I want to see the result in cases recently and at present under treatment. In closing I wish to call attention to the advantages I claim for my set of olives. In one set of instruments there is, 1st, a set of bougie à boulé for locating stricture. 2. A set of sounds for curing stricture by dilatation. 3. A set of electrodes for curing gleet with electrolysis, and 4th, a set of electrodes for curing stricture with electrolysis. They were made for me by H. C. Sample, of Chicago.

Of course there is so much more notoriety and surgical ability (?) displayed in cutting a stricture than in curing it by dilatation or by electrolysis, that though the operation is more dangerous and though it does leave the patient with a deformed penis in many cases, it will continue to have the most followers.

But for my part, having tried the different methods, I shall hereafter confine myself when possible to electrolysis and dilatation with short sounds.

I think this will be the opinion, too, of others who will give the method, especially electrolysis, a thorough intelligent trial, provided they understand the use of electricity.

But on the table before me is the May number of the *Western Med. and Surg. Reporter*, and under the heading "Electrolysis," a professor of surgery discourses on the uses of electricity, closing his article as follows: "We would at no time use more than 75 to 100 milliamperes for stricture of the urethra." He certainly would not—on the same patient.

CONTAGIOUSNESS AND INCUBATION PERIOD OF SCARLET FEVER.

BY C. G. BACON, M.D.,

OF FULTON, N. Y.

MEMBER OF THE OSWEGO COUNTY MEDICAL SOCIETY; THE NEW YORK CENTRAL MEDICAL ASSOCIATION; NEW YORK MEDICAL SOCIETY AND ASSOCIATION; AMERICAN MEDICAL ASSOCIATION.

For the last forty of the over fifty years of my practice in the medical profession, I have not doubted the contagiousness of scarlet fever. I will give a very few of the many evidences I have had to justify my conclusions. My observations have been over several hundred cases of scarlet fever, and I do not remember of a case where the invasion has been less than the seventh or the eighth day after the exposure. In cases where I have been called to attend a case evidently contracted away from home, and others of the family predisposed by not having had the disease, have advised preparation to be made for the care of the others, that would probably be taken sick in eight days after, and dieting recommended, to commence in six days from the day of exposure, as I have often observed a mor-

bid appetite for one or two days previous to the invasion of the disease.

1. In the autumn of 1849, I visited two sick children of S. Hart's. Had not seen or heard of any case of scarlet fever in the village for some months previous. They were suffering from sore throats, chilliness, nausea, etc. Among other things advised for their relief, were ears of corn put into hot water, taken out, surrounded with napkins and placed to the sides, legs and feet of the children for a short time, or until the chills should subside. At my visit the next morning, the children were covered with the scarlet efflorescence. Ten days after, a child residing in a house adjoining had the disease developed, and soon after the disease appeared in different parts of the village, as there was no strict quarantine observed.

2. The ears of corn mentioned, were the next morning given to the pigs, four in number, weighing about 60 lbs. each. Eight days after eating the corn the shoats were all taken sick, with swelled throats, so that it was with difficulty they swallowed the best prepared food. Their bodies became scarlet, three of them died in from one to three weeks, all apparently suffering all the symptoms usually seen in the human subject.

3. In the evening of the 18th of January, 1868, I visited the son of J. D. L., of this village, O., aged 14. He was suffering an invasion of scarlet fever of the anginose form. He had, on the 8th and 10th, visited a cousin at Baldwinville, twelve miles distant, sick with scarlet fever. At this time there were no other cases in this village. On the 26th two of his sisters were taken sick with scarlatina, one aged 12, the other 8. The 28th inst. his brother Frank, aged 10, and another sister aged 5, were also invaded with scarlatina. All finally recovered.

4. Across the road from this family lived Mr. R. P., whose son I saw on the 6th of February, 1868. He had a chill, nausea, etc., rash appearing on the same day. On the 14th inst. five others of the brothers and sisters were sick, with the disease fully developed, all finally recovering. One of the girls was very sick, and did not swallow food for some days, and finally was fed milk by the aid of a soft rubber hose for two days, introduced into the stomach. During the stage of desquamation of this one, had the skin from the palms of her hands, with two of the nails of her fingers, exfoliated whole or nearly so, which I kept some time as a rare specimen. From this time the disease spread rapidly through the village and vicinity. During the winter and spring I treated 68 cases, and others treated many more. There were five practitioners in the village.

5. Mrs. S. F., a widow, the mother of one son and one daughter, living in the country, went one-half mile and took care of Mrs. Morse's sick child one night (the 13th of February, 1868),

returning home afoot through a deep snow in the morning. On the 21st her two children, not otherwise exposed to the disease, sickened with scarlatina. The girl, aged 4 years, died the same evening in convulsions. The boy recovered.

6. The daughter of I. S., aged 14, attending school at the Falley Seminary in this village, her father's family living one mile in the country, was taken sick and carried home the 2d day of March, 1868—vomiting, febrile irritation, etc. I saw her in the evening at her father's house. The disease developed in a grave form. After a severe sickness she recovered. On the 10th inst. one brother, one sister, and two grandchildren of I. S., living in the same house, were taken with the disease in a milder form—simply, we claimed, owing to care and dieting in anticipation of, or preparatory for, scarlet fever.

7. On the 1st of October, 1878, a son of Prof. W. H. C., aged 6 years, sickened with scarlet fever. On the 8th inst. a sister not otherwise exposed, aged 4, had the invasion of the disease. On the 14th the babe, aged 16 months, was taken ill of the same disease. All recovered.

As this paper is getting lengthy, I will cite no more evidence of the contagiousness and the incubation period at present. I well recollect the time when the contagiousness of this disease was doubted by many in the medical profession. That scarlatina is a contagious disease is generally believed at this time. It is not caused by sewer-gas, cesspools or malaria (neither is diphtheria), although when either of these are present, it does without doubt add to the severity of the disease.

SOME INTERESTING POINTS IN AN UNUSUAL CASE OF ANTEFLEXION, WITH OTHER ANOMALIES.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY JULIA W. CARPENTER, M.D.,
OF CINCINNATI, O.

Exceptions are often as valuable aids to diagnosis as rules. Were there no exceptions, medicine would be an exact science, and instead of having only the average result for a starting point in all cases, every diagnosis would be as certain and easy as mathematics.

Prominent among the causes of sterility are anteflexions, extremely small os and conoidal cervix; the last stated by some authors to be the most common of all. Any one of these alone being a sufficient cause, what would be thought of a patient having all three of these peculiarities? Many cases like the following would necessitate rewriting all the text-books.

Mrs. H., 33 years of age, came for an examination for this reason. She was troubled at

times with a cramp and "burning sensation" in the right thigh, in a place about the size of a hand. Having tried various remedies without affording relief, she wondered whether it could in any way be due to some internal trouble. An examination revealed the following conditions: A sharp antelexion at the junction of the cervix and body, a greatly elongated, conoidal cervix, nearly 2 inches in length, with an os of the very smallest size.

Close questioning elicited the following information: She had never had dysmenorrhœa to any extent, nothing that could be called pain, only a little discomfort at first, and that had grown less each year. She had never had uterine catarrh, nor any symptoms to call her attention to the internal organs. Were it not for the cramps referred to, an examination would never have been thought of. I explained to the patient her formation, and told her the rule was that a person with any *one* of those peculiarities did not have a family, and that having all three, her prospects were not great.

To see whether the cramp complained of was a reflex from some internal pressure, a few weeks' treatment was given, but it made no change in affairs. Electricity applied to the affected limb gave some temporary relief.

A year later she returned for another examination, and was glad to be told she was pregnant. Two other physicians saw her between that time and the birth of her child, and each one spoke to her of the peculiar cervix.

The birth of the child occurred in another city, but the report was as one would expect. The first stage was very tedious, lasting three days, though there were no severe pains.

The contractions of the second stage accomplished nothing. The patient was closely built and fleshy. Instrumental interference proved necessary, with high application of the forceps. The weight of the child was 10 lbs. The mother made a good recovery.

The patient was lately seen again, when the child was 2½ years old. The cervix is now of ordinary length, and a very slight antelexion exists at the junction of the cervix and body. A laceration on the left side extends nearly the length of the cervix, but there is neither catarrh nor erosion, and the patient says she is in good health.

Another interesting point is that the cramp and "burning sensation" in the limb grew much more severe before the birth of her child, but since that event, it has never returned, indicating that it was without doubt a reflex from the peculiar internal conditions.

LENNOX BROWNE confirms the statement of Couldrey as to the efficacy of sodium salicylate in the milder forms of diphtheria.—*Journal of Rhinology*.

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

First Annual Meeting of the Electro-Therapeutic Association, held in Philadelphia, September 24, 25 and 26, 1891.

(Continued from page 889.)

FIRST DAY—EVENING SESSION.

The meeting was called to order at 8:15, with President Massey in the chair.

The first thing on the programme was a paper by Dr. Horatio R. Bigelow, on

EIGHT MONTHS WORK AT THE FREE DISPENSARY FOR WOMEN, PHILADELPHIA.

During the days of my apprenticeship in gynecological electro-therapeutics, now ten years ago, more especially after association with Dr. Apostoli, I saw that for purposes of observation and study, individual clinics were a necessity. In Europe, almost every docent has his own dispensary, giving him wide range of observation and a larger opportunity of weighing evidence than those who depend upon a fluctuating private practice. On January 1, 1891, Dr. Massey and myself inaugurated one clinic for the treatment of the diseases of women by electricity, at 1632 Cherry street. It seemed desirable to have some place where the method of Apostoli could be demonstrated to onlookers or skeptics desiring clinical evidence. Another purpose in view, which the number of cases amply subserved, was accuracy, quickness and honesty in diagnosis; an experience as elaborate as that possessed by most men, and exceeded by none, ample leisure, opportunity, and the desire to learn. A personal observation of six years in many of the large hospitals, public and private, on the Continent, convinced me that gynecological diagnosis was generally a vocative quantity among recent graduates and general practitioners. College teaching was a matter of book lore only; the educated touch came only with ample practice among a large variety of cases, and such a clientele was not always available. These things impressed themselves upon me, embarrassed me, mortified me. I knew of mistakes being made by men nursed upon theory alone, and others by men highly placed as specialists. Not the least that I learned of Apostoli was refinement, scrupulous care and precision in formulating a diagnosis. I consider him the most accurate diagnostician on the continent, and the equal of any of his peers. I was fortunate in having Dr. Massey enter readily into the scheme, for there are many responsibilities and trials in the orderly arrangement of a clinic. We have had, up to this time of writing, 75 new cases—a small number, perhaps, but

large when remembered how long a time must elapse before such a place becomes generally known, and how loath charity patients are to engage in a new medical department. We have made between 600 and 700 applications, as follows:

Anodal galv. vaginal	275
“ “ uterine	250
Cathodal galv. vaginal	
“ “ uterine	25
Anodal vaginal galv. lahile	1
Bipolar vaginal faradic	4
Puncture through vagina positive	10
“ “ “ negative	45
“ “ abdominal walls	3

These punctures were all for uterine fibroids. Three tumors were subperitoneal, the others mural. There were fifteen cases of fibroids. The mean current strength used for vaginal applications, 35 mm.; for punctures, 85 mm. Five cases of specific, purulent salpingitis, five of salpingitis—and by this, I mean cases which had no specific history, in which there was no cachexia, no hectic, and in which the pains were not important—five cases of salpingo-ovaritis, or cases in which we believed there was a series of pus pockets in the tubes and ovaries. As much as we would like to puncture some of these tubes, in which the drainage to the uterus was free, no pus pockets being present, we were unable to do so, because there were no beds at our disposal. Symptoms are relieved by vaginal applications in simple forms, but cases are never cured. The intra-uterine applications, supplementing the vaginal, do have a marked influence for good, in simple uncomplicated cases, those in which the tubes are not constricted and those forming abscess pockets, and where the dribbling into the uterus has not been interfered with. The cases of large tortuous tubes, with thin and distended walls, irregular swellings, denoting pus pockets, and pronounced cachexia, demand the interference of the surgeon. Electricity can do no possible good—it may do much harm. So one object of a well conducted clinic is differentiation; to know what cases to treat, to realize that there is such a thing as over-treatment, and that electricity is not a panacea for all female pelvic disorders. Some other things are learned. Many tumors appear benefited symptomatically only. Soft myoma, fibroma undergoing degeneration, and subperitoneal tumors, are not benefited anatomically, as a rule. We had one case of a large subperitoneal fibroid—that of Emma Howard—sent us by the County Medical Society, which has been punctured a dozen times through the vagina, without apparent diminution of the growth, and without decided change of symptoms. Locomotion is difficult and painful. This was an unfortunate test case, because subperitoneal growths, being far out of reach, resist the action of the current, and the patient's surroundings are most

lamentable. She is a type of poverty. She lives in filth, is insufficiently nourished and drinks to excess. Confidence in any therapeutic measure should not weaken one's honesty in the recapitulation of results. In this case, Dr. Massey has tried electrolytic puncture with three needles through the abdominal parietes. We know statistics are against this mode of treatment, and I am not convinced that there has been any diminution of the growth of the tumor. It has changed its form from a prominent, dome-like swelling, to a spread out, lobulated lateral mass, somewhat lower down in the pelvis. While abdominal puncture, theoretically, might be proper, the results of operation are against its use. Where the abdominal walls are as thin and transparent as in the case of Emma Howard, where the intestines are not overlying the tumors, and the bladder at a safe remove, I do not see why abdominal puncture may not be given further hearing. All of our cases of fibroids were made comfortable, notably that of Mrs. Clarke, who has a left lateral fibroid low down, and who says punctures only give her relief from the symptomatology. No tumors have disappeared. Two, Hester Wilson's and Mrs. Clarke's, are reduced in size. Under better hygienic conditions and regular treatment, I feel sure we should have better results than is possible in a clinic. Many cases come irregularly for treatment, and are not under constant observation; and all badly nourished and improperly cared for. Small intramural tumors, hard and not very painful, that are taken in hand as soon as noticed, always do well under the buried negative puncture, and I believe may be made to disappear, although I have never seen such a case myself. Inflammation of the adnexæ, old chronic salpingo-ovaritis, demand the greatest possible care and dexterity in their management. Of the first importance is accurate diagnosis. It is a *sine qua non* of success, that the electro-therapist be a thoroughly competent gynecologist, if he intend limiting his practice to the diseases of women. This can only be acquired after years of work in large clinics where the material is ample, and it would be well for the science and art of medicine if a more enlightened view of pathology should be conjoined to it. We ought to know all about the processes giving rise to abnormal conditions, that we may have a clear conception of the limits and degree of acute inflammations, and of the nature and extent of degenerations. Otherwise we grope in the dark, and our labors will be in vain. Pathology is far too commonly neglected. In acute diseases of the adnexæ, the introduction of a sound, even in competent hands, is apt to create mischief. Not only is the lining membrane of the tubes in a hyperæmic and hyperæsthetic condition, but the whole endometrium, and it is bad practice to resort to any measure which shall in-

tensify such pathological processes. In some chronic states this may hold true. I believe the reputed cases of active inflammation of the peritoneum after application of intra-uterine current have been so caused. I have recently had one case myself. I knew better, and operated much against my better judgment, and my patient had a fight for life for many weeks. It was a bad case of salpingo-ovaritis, in which I advised surgical intervention, because I felt that nothing but the knife would give permanent relief. But the patient would have none of it. I gave her the application within the uterus of 30 mm., which was well tolerated, but it awoke the fires at once, and I had a hard battle for eight weeks. It has taught me a lesson. Hereafter I shall inaugurate the treatment in such cases by vaginal applications of great delicacy, until I am satisfied that the patient's uterus will be tolerant of a foreign body, and in all cases of extremely tortuous or constricted tubes I shall decline to interfere. I firmly believe in the value of electricity in gynecology; I am as ambitious for it as any one can be, but I realize that incompetence, immoderate enthusiasm and faulty differentiation are to be avoided. I know electricity is employed in diseases of women by those who have not the requisite experience, nor the modesty, for its successful employment. I repeat what I have often said, that faulty complications do not happen to competent electro gynecologists, and I refer any one interested to the report of the commission appointed by the Academy of Medicine of Paris to investigate the fatal results in the practice of electro gynecologists, which will be found in the July number of the *Revue Internationale d'Electro-thérapie*.

As to the question of adhesions. Any inflammatory process in the pelvis will be followed by some effused lymph which may formulate as an adhesion. In fact almost all tumors I have seen operated upon were complicated with adhesions, and these too happened in countries where electricity had never been employed. The thoughtful student will see that such an objection cannot possibly hold, excepting the case I have cited. We have had no bad results in our clinic. One interesting case came to us from Dr. Thomas of New York. The late Dr. Schroeder, of Berlin, diagnosed an exudate, so did Carl Braun, of Vienna. Dr. Joseph Price of this city opened the abdomen, but did not complete the operation, because he did not have the patient's permission to do a hysterectomy. Dr. Thomas diagnosed an intra-mural fibroid. The woman is exceedingly fat, the vagina long, and an exact diagnosis is arrived at with difficulty. There is apparently a small tumor, but there is also an exudate, through which one can make out the tumor. The left lateral fornix is filled up with a boggy mass, extremely sensitive; the tube can-

not be felt, and I am not sure that I made out the ovary on that side. She has frequent attacks of severe pelvic pain. Coition is always painful. At her menstrual periods she has great suffering. We have been treating her unsuccessfully with vaginal applications. We now commence the intra-uterine application, because I find a sound is well tolerated. Another subject which I would touch upon. We are over-inclined to judge of the work of surgeons engaged in abdominal surgery, either from inadequate observation or from a study of those cases only which come under our personal observation, or from discussions in medical societies, or worse still, one's conclusions may be drawn from the unsound reasoning of a one idea personality. I believe many tubes and ovaries are removed without sufficient cause, but these instances are not often out of the record book of those competent to practice abdominal surgery, but usually are the belongings of a young ambition, anxious to climb. Surgery is handicapped with incompetent practitioners just as our own specialty is, and it is not one more logical to lay miserable failures and mistakes at the door of honest surgery, any more than for surgeons to conjure all sorts and conditions of doubts and to hold the responsible intelligences among electro-therapeutists responsible for engendering them. We must remember that eminent surgeons see a class of cases, and those in large numbers that rarely if ever come to smaller clinics. Cases in which nothing but operative interference could be of the least service. So we may not wonder that surgeons arise in their wrath, when lesser lights, who know little or nothing of such aggravated forms of disease, dispute the necessity of operating. The cases that I have recently seen operated upon by Dr. Joseph Price, were those of enlarged constricted tubes, an abscess in fact between each constriction, with an abscess in the ovary. Electricity could do nothing. Neither would an expectant plan of treatment be of service. Electricity would be most pernicious because only one pus pocket could be reached. I know there are now, and always will be, cases which will not be benefited by electricity, and one of our greatest dangers is the over claiming of young and restless men among us, and the unequivocal condemnation of honest intelligent surgery by those who know little of either abdominal surgery or electro-therapeutics. We will gain nothing but enlarged advertising by the loss of dignity and self-respect that must come from the unseemly debate that sometimes happens in our medical societies. Personalities are offensive, and are not arguments. Honest surgeons do not rail at us, but they do object to inexperienced gynecologists and unlettered electro-therapeutists claiming marvels for a method of which they can know little or nothing. And they have a right to ob-

ject to the criticism of men who know nothing of pathology. I deprecate the tone of recent discussions in special societies. I shall keep on doing my work in electro-therapeutics in the best way that I can, and I expect surgeons to believe that I am acting intelligently and conscientiously. I have served a long apprenticeship both here and abroad—quite as long as any of them—and I say it with modest intent, I feel quite as competent to judge of the necessary treatment in certain cases, as they. They must not impugn my motives, they cannot impugn my intelligence. I know that a study of electricity is fraught with difficulty and is not to be had for the asking, and I know too that there are very few operating surgeons who know anything about it. Therefore they are not competent witnesses.

(To be continued.)

Southern Surgical and Gynecological Association.

Fourth Annual Meeting, held in Richmond, Va., November 10, 11 and 12, 1891.

(Concluded from page 893.)

NOVEMBER 12, THIRD DAY—MORNING SESSION.

The Association was called to order by the President at 10 A.M.

Dr. James A. Goggans, of Alexander City, Ala., read a paper entitled

ABDOMINAL SECTION IN A CASE OF CYST OF THE MESENTERY.

He stated that he had been induced to write a paper on the case from the fact that cysts of the mesentery are extremely rare, and that operations for their removal are most generally fatal. He said that he had been able to find the record of one case of cyst of the mesentery removed by enucleation by Guyon. The patient died on the seventh day after the operation. One case operated upon by Sir Spencer Wells—the operator in that case incised and drained the cyst, but the patient died within a few weeks. Three cases operated upon by Péan, only one of which recovered. One case operated upon by Watts, but that he did not know the result in the case. One case operated upon by Cortes, who incised and drained the cyst, but the patient died from septicæmia and hæmorrhage. One case operated upon by Bantock, who removed the cyst by enucleation, and the patient recovered. The conclusion arrived at as to the origin of the cyst in that case, both by Dr. Bantock and the pathologist who examined the specimen, was that it originated from some fœtal structure, possibly some of the rudiments of the permanent kidney. He said that Dr. Greig Smith says that he knows of two cases of mesenteric cyst removed by opera-

tion by his friend, but that he could not relate them to him, as they had not yet been published. He said that the patient upon whom he had operated for a cyst of the mesentery was a young woman, 21 years of age, daughter of a physician of Columbus, Ga. She had not been well for two years, but did not know that her abdomen was becoming larger until three months before the operation. During those three months she had been treated for abdominal dropsy, and had suffered much uneasiness and pain in the abdomen, and at the time of the operation her pulse was 120, and temperature 100° Fahr. The cyst was quite large, occupied mostly the left side of the abdomen, extended from under the ribs into the left lumbar region, dipped downward into the pelvis, and extended 3 or 4 inches beyond the median line of the abdomen into the right side. He said that he first removed about a quart of the fluid by aspiration on February 7, 1891. The fluid was thin and of a dark color, and contained albumin, phosphate and chlorides. The patient was not benefited by the operation, and the abdominal section for the removal of the cyst was made on February 24, 1891.

The cyst was covered with omentum and mesentery, and loops of small intestine were embedded in its walls. An attempt was made to enucleate it, but hæmorrhage was so free that the idea of enucleation was soon abandoned. A point as remote as possible from blood-vessels and intestines was selected, the cyst incised and drained. More than one gallon of a thin, dark-colored fluid was evacuated, the sac irrigated with hot water, the lips of the incised sac stitched to the upper angle of the abdominal incision, and a glass drainage tube introduced to the bottom of the cyst. The abdominal incision was then closed with silkworm gut sutures. The author was confident that the cyst was retroperitoneal. The time consumed in the operation was twenty-five minutes. The sac was irrigated three or four times in the twenty-four hours, and the drainage tube gradually withdrawn. The patient suffered much from nausea and vomiting, which he attributed to the close connection between the walls of the sac and the loops of small intestine. The patient made a good recovery within thirty days. He presented a picture of the patient which was taken the 1st of November, 1891, which showed her to be in perfect health.

THINNESS OF UTERINE WALLS SIMULATING EXTRA-UTERINE PREGNANCY, WITH REPORT OF TWO CASES,

was the title of a paper by Dr. Geo. J. Engelmann, of St. Louis, Mo.

The author said there are many difficulties in the way of a positive diagnosis of early pregnancy, even in cases surrounded by conditions less unusual, but they assume alarming propor-

tions when aggravated by the curious complications which may arise in individual cases, and above all when conditions are simulated in which delay is dangerous and operative interference seems called for, when a decision is urgently demanded, a decision upon which a life, and perhaps two, may depend. Whilst the auditor may criticise at his leisure, and readily differentiate the conditions depicted, it is only he who is to pronounce and to act who can realize the difficulties of this so entangling and knotty a problem.

Case 1.—Patient, 32 years of age, had borne three children in the six years and a half of her married life, the youngest 20 months old, which she was still nursing, and the menstrual flow has not as yet reappeared since the birth of this child. The patient came to his clinic for relief from a variety of discomforts from which she had been suffering more or less for the past three months. She complains of sick headache, vomiting spells, fulness of the stomach, belching after meals, and an intermittent swelling of the abdomen, a pain in the groin, appearing before such swelling, and a small tumor above the right groin, which she had first noticed three weeks ago, and as she stated, then suddenly made its appearance. An examination revealed large varicose veins over the lower limbs, a solid, round, movable tumor above symphysis and right groin, the cervix low and large, the uterine body thickened, lying low in the pelvis, with a certain mobility independent of the superimposed tumor, an applicator entering $3\frac{1}{2}$ inches slightly *ante*. Notwithstanding the wine color of the pronounced cystocele and the cervix, pregnancy seemed out of the question, and the tumor was diagnosed as most probably a dermoid of the right ovary, hardly one connected with the uterine wall. In the course of an examination two weeks later, a very different condition of affairs was revealed. The tumor had disappeared, and a foetus was found in the utero-vesical space, freely movable, apparently floating about, the small parts being distinctly felt as if underneath a wet towel, both through the vaginal and abdominal walls. So distinct did the small parts appear to the examining finger, that it seemed impossible to realize that even as much as a thickness of the vaginal tissues should intervene, and the abdominal walls must certainly have been very much attenuated to disclose the foetal parts with such distinctness. Probe showed the uterine cavity free, $6\frac{1}{2}$ inches in length, still slightly *ante*, but never curving forward in the direction of the previous tumor.

The treatment for the supposed subinvolution was discontinued, the patient warned to keep quiet, and to notify Dr. Engelmann upon the occurrence of any abnormal symptoms. He believed the case to be one of ectopic gestation, either within the broad ligament or in the ab-

dominal cavity, after tubal rupture marked by the sudden appearance of the tumor five weeks ago, yet he was not sufficiently positive to warrant the immediate resort to the knife, and well that he did not do so, as persistent treatment and repeated examinations resulted in labor pains, and the delivery of a five months foetus in the most correct and natural manner.

Dr. Robert T. Morris, of New York, contributed a paper on

THE REMOVAL OF NECROTIC AND CARIOUS BONE WITH HYDROCHLORIC ACID AND PEPSIN.

The author said sometimes it is desirable to remove dead bone without subjecting a weak patient to a dangerous or deforming operation. Attempts have been made with some success at clearing out this bone by a process of decalcification, but there are two chief reasons why failures have resulted as a rule. In the first place, it was discovered that superficial layers of dead bone were decalcified easily enough, but the acids did not reach deeply through the mass, especially if portions were infiltrated with caseous or fatty debris. In the second place, cellulitis was pretty apt to develop during the course of treatment.

After much experimentation, he had finally adopted a method of work which seemed to be complete. An opening is made through soft parts by the most direct route to the seat of dead bone, and if sinuses are present, they are all led into the one large sinus, if possible. The large direct sinus is kept open with antiseptic gauze, and the wound allowed to remain quiet until granulations have formed. Granulation tissue contains no lymphatics, and absorption of septic material through it is so slow that we have very good protection against cellulitis. The next step consists in injecting into the sinus a two or three per cent. solution of hydrochloric acid in distilled water. If the patient is confined to bed, the injections can be made at intervals of two hours during the day; but if it is best to keep the patient up and about, the acid solution is thrown into the sinus only at bed time. In either case, the patient is to assume a position favorable for the retention of the fluid. Decalcification of exposed layers of dead bone takes place quickly, and then comes the necessity for another and very important step in the process. At intervals of about two days, an acidulated pepsin solution is thrown into the sinus (he uses distilled water, 3iv ; hydrochloric acid, m. xvi ; Fairchild's pepsin, 3ss), and this will digest out decalcified bone and caseous and fatty debris in about two hours, leaving clean dead bone exposed for a repetition of the procedure. The treatment is continued until the sinus closes from the bottom, showing that the dead bone is all out.

Even in distinctly tuberculous cases the sinuses will close if apparatus for immobilizing diseased

parts and tonic constitutional treatment are employed, as they should be, in conjunction with our efforts at removing the dead bone. If supuration is free in any cavity in which we are at work, it is well to make a continual practice of washing out the cavity with peroxide of hydrogen before each injection.

It is a popular impression in the profession that living bone is not attacked by dilute mineral acids, but as it makes a good deal of difference whether the impression is correct or not, he experimented as follows: A portion of the keratinoid layer was removed from the carapace of a turtle (*nanemys guttatus*), and the animal was then placed tail downward in a glass of five per cent. hydrochloric acid solution. In the glass he placed also a segment snipped from the plastron of the turtle, and a transverse segment from an old dry humerus of a man. The piece of humerus was completely decalcified in six hours; the segment from the plastron was soft in about twenty hours, and the carapace of living bone was decalcified at the exposed part in thirty hours. He was then curious to know what effect the acid had had upon the blood vessels of the decalcified bone, and Dr. Smith, of the laboratory of the Post Graduate Medical School, made for him several sections of the carapace, which included both decalcified and healthy bone. Investigation showed that all of the blood vessels were destroyed wherever the bone was softened, and the action of the acid had extended farther up along the larger blood vessels than elsewhere.

The difference in time between decalcification of the dead bone—six hours—and of living bone—thirty hours—is significant; a five per cent. solution of the hydrochloric acid having been used. If we use a two or three per cent. solution of hydrochloric acid, a wall of lymph and of granulation tissue is thrown out upon the surface of the living bone for protection, and only dead bone is attacked. This, at least, has been his observation in several cases in which the results of treatment could be easily watched.

Dr. Landon Carter Gray, of New York, in a paper entitled

THE PRESENT STATUS OF CEREBRAL SURGERY, touched upon the modern aspect of intra-cranial surgery. The speaker first passed in review our present knowledge of localization of functions of the brain, stating that we were well acquainted with the functions of the motor area, of the third frontal convolution, the frontal lobe, the island of Reil, the two upper temporal convolutions, the cuneus, certain portions of the basil ganglia, the base of the brain and the cerebellum, and that we knew nothing, or had still under discussion the question of the localization of the centers for the sensations of touch, pain, muscular sense, temperature sense, most of the parietal

lobe, and most of the temporo sphenoidal lobe, with the exception of the olfactory lobe. He stated that operations for fracture of the skull with or without hæmorrhage, for abscess, and for tumors that were removable and localizable, were usually successful; those for so-called idiopathic epilepsy were utterly valueless, as were also those for epilepsy supposed to be due to genital or ovarian irritations, whilst those done for epilepsy due to removable and localizable lesions of the intra-cranial contents were usually successful so far as the lesion was concerned, although it was a grave question as to whether the epileptic habit was ever cured; the latest operation for idiocy supposed to be due to premature ossification of the fontanelles was still under discussion and consideration, the cases being too few and too recent to permit of any conclusion, while the operations for hydrocephalus and for epilepsy due to such early infantile and foetal lesions as porencephalus, hæmorrhage and meningitis, were indefensible. He further impressed upon surgeons the great difficulty that there often was in finding a sub-cortical lesion of the centrum ovale that was deep-seated or small, and the fact should be borne in mind that there might be no discussion of the motor fibres from the hemispheres, so that a lesion would be found upon the same side as the paralysis.

Some Complications of Psoas Abscess.—This was the title of a paper read by Dr. McF. Gaston, of Atlanta, Ga.

THE ANTISEPTIC ACTION OF SALOL.—As the result of a series of experiments with salol, Dr. F. Papuli arrives at the following conclusions:

Salol has pronounced antiseptic properties, especially against certain microorganisms. Its antiseptic action is due to its decomposition, which is produced by the microorganisms themselves. All microorganisms decompose it, but those which decompose it the most actively lose their vitality, while those which only partly act upon it become attenuated, and finally, those which influence it but slightly remain active.

Finally, salol has an important influence upon suppuration. Although this was well known in medical practice, as, for example, in cystitis and pyelitis, as well as in surgery, these experiments would seem to present a clear explanation of its favorable action. While all the writers in their publications speak in general of an antiseptic action, and Gratzel of a detersive and exsiccating influence, from experiments, one comes to the conclusion that the antiseptic action of salol upon suppuration consists in the property which pyogenic microorganisms have in decomposing it and remaining inactive after its decomposition. Its action upon the surfaces of wounds may be considered as double; the salol in the inferior stratum decomposes and renders the cause of suppuration powerless; while, in the superior, salol being, like iodoform, insoluble, it protects the wound from external agents, remains unaltered in the secretions of the wound, while those secretions which contain microorganisms are disinfected.—*Annals of Surgery.*

WHITE of egg is said to be an efficient application for sore nipples.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, DECEMBER 12, 1891.

RUPTURE OF THE UTERUS.

This appalling accident, although, fortunately, rare, happens with sufficient frequency to make it a matter of concern to all obstetricians. Particularly is it desirable to remember the conditions most frequently leading to it, and to be familiar with such premonitory signs as are occasionally afforded.

DR. J. M. WITHROW, of Cincinnati, has reported, in the last number of the *Lancet-Clinic*, a case apparently unique in some particulars, and which emphasizes with unusual force the part played by ergot in this disaster. Hastily summoned to see an obstetric case, he was informed, upon his arrival, that the woman was dead. Finding a suspicion of heart movement, he immediately gave a hypodermic injection of tincture of digitalis; then examined *per vaginam*, and found the cervix fully dilated, and the vertex presenting, but not engaged. The pelvis was roomy and the head small, so that in about five minutes delivery by the aid of the forceps was effected. The child was a male, weighing five pounds, and was dead; in fact, had been dead for some time, the skin easily slipping off. After removing the placenta, he was much surprised not to be able to find a rupture of the uterus, which he had suspected. The patient, a healthy

woman of 37, had reached full term with her seventh child. Labor commenced at 1 P.M., at which time the midwife was sent for, who stated that the "womb wasn't open." At 3 P.M. she returned, and, finding the womb still closed, gave the patient, according to the statement of a neighbor, a teaspoonful of a dark liquid, which she said would hurry up the pains. Soon after this, she had "one long, hard pain," of which she loudly complained, and not long after that she began to faint, which she did frequently until she died, at 7.30 P.M. The midwife denied that she gave the patient any medicine, but the statement of the neighbor, taken in connection with the resulting symptoms, and the fact, according to DR. WITHROW, that the administration of ergot is an almost uniform practice among the midwives of that city, will leave but little doubt in the minds of practitioners on this score.

Seventeen hours after death an autopsy was made. To use DR. WITHROW's words: "The tissues were almost completely exsanguinated. Upon opening the abdomen, the peritoneal cavity was found full of free blood and clots, which measured ten pints. The uterus presented a most extraordinary spectacle. It was ruptured from a point on the anterior surface midway between the points of insertion of the Fallopian tubes in the median line, extending up over the fundus and down the posterior wall clear into Douglas' fossa, a distance, even in the collapsed and empty uterus, of nearly twelve inches. The general direction of the tear was straight, but the edges of the split were decidedly ragged. The strange part of the injury, and peculiar to this case, so far as has been ascertained, is the variety of the incompleteness of the rupture found in this specimen. The mucous membrane of the uterus was not torn through at any point, but the peritoneal and muscular layers were severed through the entire length of the rupture. This accounts for my failure to find a rupture by introducing the hand after delivery. When the uterus was taken out it was filled with water, which it held without a leak."

The uterus ruptures when the force of its contractions become greater than its resistance. The etiological factors therefore are to be found in the conditions which stimulate the uterus to excessive effort or conditions which diminish the

strength of the organ. That the latter element is a particularly important one, is shown by the fact that the great majority of ruptures occur in late confinements, especially the fifth or sixth, when it may be presumed that the uterine tissue has lost some of its original tensile strength, even if definite changes can not be demonstrated. In some instances excessive fatty change of the muscular tissue has been shown to exist. It has been found to occur in the cicatrix of a Cæsarean operation. It is hardly possible that without some such essential weakness the uterus could ever be stimulated to such excessive action as would produce rupture. In an overwhelming number of cases mechanical obstruction to the birth of the child is present. These obstructions are to be found in contracted pelves, particularly those in which sharp spinous deformities exist; in cases of unusually rigid cervix; in malpresentations; in excessive size of the child. It has occurred so frequently with hydrocephalic children as to make this condition one of peculiar danger to the mother on this account.

IN DR. WITHROW'S case, however, the child was small, weighing only five pounds, and the pelvis was roomy, and had afforded a sufficient outlet to six previous children, and the presentation was normal, so that excessive uterine action from mechanical obstruction could not be blamed for the result. The uterine stimulant was supplied, however, artificially by the ergot, and this agent produced a contraction so long and so violent as to cause the rupture. Why the ergot contraction should result in rupture rather than in the expulsion of the child, in the absence of mechanical obstruction, is not at first clear. But the open cervix found by Dr. WITHROW, several hours after the accident, was not the condition at the time when the midwife administered the ergot. Immediate dilatation of the cervix was not possible, and the weak uterine walls gave way. The hard small parts of the fœtus, the knees, feet and elbows being against the uterine walls. According to MADAME LA CHAPPELLE, "some of the muscular fasciculi act in the wrong direction, whilst others, finding a firm support, contract with greater energy." Hence, even with an open os, rupture may occur under ergot stimulation.

The estimate of HARRIS that rupture of the

uterus occurs once in about 4,000 labors, is probably very much under the truth, and the accident should not be regarded as too rare for ordinary consideration, but the possibility of its occurrence should always be borne in mind when predisposing factors are present. When rupture is imminent, the uterus should be emptied as quickly as possible, but it should not be forgotten that the additional tension, following the application of the forceps or the introduction of the hand in the uterus for turning, has been the immediate cause of the accident. Craniotomy is less dangerous under these circumstances than the simpler operations. The case reported by Dr. WITHROW is peculiar in the character of the rent, which prevented certain of the classical signs, recession of the head, and flattening of the bag of waters, from showing themselves. Its great importance, however, is the clearness with which it illustrates one of the dangers of ergot.

RESTRICTION OF IMMIGRATION.

The continuous rapid increase of immigration to this country furnishes our Nation's statesmen with a subject worthy of their most profound consideration. The number of immigrants from 1789 to 1820 was 225,000; 1820 to 1830, 143,400; 1830 to 1840, 599,100; 1840 to 1850, 1,713,200; 1850 to 1860, 2,598,200; 1860 to 1870, 2,466,700; 1870 to 1880, 2,944,600; 1880 to 1890, the enormous number of 5,176,200, the vast majority of whom seek homes or places of habitation in the cities, and this particular city is said to be receiving of this number now, more than 60,000 per annum, while the whole number of 5,176,200 is equal to one-twelfth of the entire population of the United States, and greater than that of the second State in the Union, and more than three times as great as the Nation's metropolis. When we contemplate the character of these immigrants, we are appalled and shrink from our own thoughts.

The first settlers of our land were people who came here, perhaps most of them, to escape the intolerance of religious persecutions in other lands. To them this was a haven of rest. From these early settlers sprang the men and women who have to this time been the governing body of American citizens. They abjured a State church, and established free schools. On these

two substantial corner stones they erected the governmental superstructure of this great Nation. The fame of the free republic was wafted across the ocean, and into every palace and hamlet.

The educated people of other lands looked upon this experimental republic as a menace to monarchical existence. The poor and ignorant heard the glad tidings of the land of the free, and longingly waited for the time when they could enjoy the blessings of so free a land.

In monarchies there are no free schools, which means very much, for where ignorance prevails, vice and crime go hand in hand. And these poor, ignorant people, who are superstitious, vicious and criminal from inheritance and association, look to America as the land where it seems to be as free for them to do wrong as to do right. This was and is with them the sole motive thought, while with their respective Governments, it has been regarded as brilliant statesmanship to get rid of those who were and are only a menace or an expense; a menace, if healthy in body, and an expense if diseased in either mind or body. Hence, we have our hospitals, asylums and benevolent institutions of all sorts filled with foreign born paupers who have, in many instances, never earned a week's board—in fact, are brought direct from almshouses and infirmaries, assisted by either friends or the paternal monarchical Governments, to this country, where they are quickly housed in our great public caravansaries.

But these are not of the worst class, although they do bring with them infectious, loathsome and incurable diseases, but the vicious and criminals. Men and women who are ready to sow seeds of anarchy and communism, falsely believing it right to do wrong, they are of the Mafia and kindred societies.

Foreign armies are kept up not so much from a fear of neighboring nations, as from a fear of the element, that go to constitute their own several nations. Young men at the age of enthusiasm, when their blood is warm, and should be most actively engaged in the industries of life, are made conscripts and kept in the army until the edge wears off, and their ardor quenched, serving out their time, they are too old to go into a revolution and have had the drill and discipline to make them reverence the King and Nobility.

Wisely and none too soon our last Congress enacted a most wholesome immigration law, which went into effect last April. The purport of this most righteous Act is to shut out all immigrants suffering from infectious and incurable diseases.

It is believed, that the act is sufficiently strong to prohibit some of the undesirable elements which under the old law were free to enter. One of the peculiar features of the new act is that it does not recognize an immigrant as landed until he has been passed by the Landing Bureau of a Department of the Treasury. The steamship companies are thus made the custodians of all persons who are denied entry for physical reasons; and they become responsible for the care and maintenance of those persons so long as the importing vessel remains in port, and on her departure she must take away the rejected material. As a natural consequence the companies have advanced their rates for steerage traffic, which, of itself, will tend to purify the stream of immigration. Another salutary influence of the new law is that the steamship companies will become more cautious about the class of people they permit to come to this country on their vessels, and it may lead up to a preliminary physical examination on both sides of the ocean, by competent medical inspectors. When this good end shall have been accomplished, a very weak spot in our international relations will have been touched—a spot that has repeatedly pointed out in our medical and sanitary publications.

In British America, medical attention has been turned to the frequent importation of leprous cases from Asia. Medical men have recently investigated such cases at Victoria, British Columbia, and have recommended that their increasingly rapid importation should be checked by legislation. It is stated that there has been a considerable spread of the disease during the last year in nearly all the Pacific cities of the Dominion, and has reached a point where its further advance must affect disastrously the prosperity of British settlements there.

At the last meeting of the American Medical Association the proposition to add a medical officer to the cabinet was freely discussed, and much has been said in its favor. To our mind, the urgent need of such an officer is shown if he

is to deal with no other subject than that of immigration, a question fraught with mighty consequences to this Nation, and beside which questions of war, famine and trade sink into comparative insignificance.

NATALITY IN FRANCE IN 1890.

It is well known that the natality in France has been diminishing since the beginning of the century, but the year 1890 was marked by an unusual decrease in the number of births. Dr. ADOLPHE BLOCH, of Paris, has sought an explanation for this in the epidemic of gripe of that year.

The number of births in every department without exception was less in 1890 than in 1889. In *La Bretagne*, for example, there were 71,867 births in 1889, and only 68,283 in 1890. The number of illegitimate births as well as the legitimate ones has diminished, being 2,777 less in 1890 than in 1889.

The greatest intensity of the gripe occurred in Paris during the months of December, 1889, and January, 1890, so that its greatest influence on natality should be found in the months of September and October, 1890. According to the statistics of J. BERTILLON, the number of births per year per 1,000 in Paris for the several weeks of September and October, 1890, varied between 18.10 and 23.80, while the average figure for the whole year was 26.90. Comparing these figures with the year 1891, which in consequence of the diminishing natality of the century, should show a slight decrease, it was found that the corresponding figures for 1891 varied between 23.27 and 27.25. The figures for illegitimate births, calculated per 1,000 marriageable women between 15 and 50 years of years of age, per year, showed corresponding relations. In 1890 the weekly variations during September and October were from 32.99 to 44.97, while in 1891 they were from 43.79 to 53.40. These figures show very conclusively that the gripe was largely responsible for the extraordinary and unusual diminution in natality in 1890.

DR. FRANK W. REILLY, of Chicago, formerly a surgeon in the Marine-Hospital Service, has been appointed Secretary of the Illinois State Board of Health.

DOMESTIC CORRESPONDENCE.

Alcohol. The Other Side.

IN THE JOURNAL of November 28, Dr. Chenery, of Boston, tells what he knows about alcohol, and the article shows that he is well posted on the subject, but I am persuaded from its perusal that the Doctor has entirely ignored the good alcohol will do in disease. His aim in writing the article was to show how much evil it would do, and this way of writing up an article is not right. Nearly all writers, it does not matter on what subject they are writing, have a point to make, and to do this they sum up all the testimony they can get to make their point, but they rarely say anything that would likely destroy the force of their argument. Dr. Chenery admits that alcohol is an anæsthetic, but for fear some one will use it for that effect he immediately tells us that ether and chloroform, etc., are much better, and not so seductive. But the doctor fails to tell us how or why they are better. His sole aim was to jump on alcohol and to make its character as a remedy so hideous that doctors would not use it. But alcohol has helped too many practitioners out of close places for them to turn it loose simply because it has power to do harm. Dr. Chenery could take up any remedy that is a poison and could say all the evil things of it that he has said of alcohol. Any one knows that all poisons are destructive. He could take opium and say just the same things of it that he has of alcohol, but the profession will not give up opium as a remedy simply because its wrong use kills people or makes them crazy. Every physician who has had any practice knows for himself what alcohol will do in emergencies, and when these emergencies arise he would not be without it for any reasonable consideration. You may preach that it is poisonous, and seductive, and dangerous, and all that, but when the proper indication arises for its administration the conscientious physician will give it, and the suffering patient will thank him for it. An anæsthetic, one that will ease pain and not *kill*, is alcohol that kind of a remedy? When a man is dying for want of an anæsthetic, when his heart's action is so feeble that his pulse is imperceptible, would you substitute chloroform or ether, nitro glycerine or nitrate of amyl, when you knew that in alcohol you had a known and tried remedy, and one that would not disappoint you nor injure your patient? When a human life is at stake give what you know to be best for your patient, and do not let some fine-spun theory of alcohol's effect on blood-cells cause you to try something you know nothing about. Of course if you have tried all the substitutes that Dr. Chenery suggests, and find them more appropriate and less dangerous, you will give them, but until you have reached this (to me) very doubtful position, give alcohol. To show how extreme Dr. Chenery is on the question of alcohol, he would advise us to go back a quarter of a century and take up the lancet. Does Dr. Chenery know what effect blood-letting has in the treatment of pneumonia? Has he ever tried it? If not, how does he know that it would be an improvement on the alcoholic treatment? Now my object in commenting on the doctor's

article is not to prove that his theory of the effects of alcohol on blood-cells is erroneous, but it is simply to warn readers of that article not to jump at the conclusion because alcohol is capable of destroying the human frame in its entirety, that it is no account as a remedy. If you recollect, it has been said of mercury that it was very destructive, and a *great devitalizer*, and that it had killed more people than it had ever cured, but all readers of THE JOURNAL will tell you, it is a very good remedy for syphilis, and they would not like to be without it in the treatment of that disease. In conclusion I will say that alcohol is a safe anæsthetic in any disease where an anæsthetic is indicated. In typhoid and all low grades of fever, in shock, in nervous prostration, in a variety of well known conditions, its use has been followed by the happiest results, then why should we not give it? It is wonderful how a smart man like Doctor Chenery will be led into the (to me) extreme notions he has of alcohol. By reference to an article in this same number of THE JOURNAL, by Dr. Everts, of Ohio, the first man he describes, on page 837, you will find Dr. Chenery's position on alcohol very well described, and if the doctor will carefully read the same it is possible he will retract some of his wild assertions. I hope no reader of this article will presume that I am in favor of alcohol as anything else than a well known and useful remedy, but I am satisfied that there are no substitutes for it except those which are equally capable of harm, and until the profession show to the contrary I, for one, will continue to prescribe alcohol.

Very respectfully,

W. P. HOWLE, M.D.

Oran, Scott County, Mo.

Insanity.

To the Editor:—Dr. Everts' paper entitled "Insanity as Related to Civilization," printed in THE JOURNAL for November 28 ult., cannot fail to excite well merited attention. His thesis is not to show the causes of insanity, but to indicate how the conditions of civilization favor the preservation and transmission of certain constitutional or organic states that may, under appropriate circumstances, manifest the symptom—insanity. How these constitutional or organic states arise, he does not attempt to explain.

It is made clear that civilization is responsible for as much of the insanity—or of the conditions which make it possible—as its fostering care can preserve; but this is not the only relation which exists between civilization and insanity. Civilization should be held more primarily and actively responsible for that potentiality (more properly *impotentiality*), which finds expression in insanity. Change of environment is the *cause* of organic variations; it is the unceasing interaction that exists between living organisms and environment that gives rise to progress, and to relative or absolute retrogression, when the organism fails to respond actively to the stimulus of environment.

Degeneracy—failure to respond adaptively to the stimulus of environment—is a biological accident. The organism manifesting it may be maintained for a time, and

transmit its *impotentiality* to succeeding organisms, but here retrogressive annihilation is inevitable. Nature has been and ever will be superior to art; she cannot be frustrated. The conditions always obtain for the production of degeneracy. If civilization had never favored the degenerate, still they would be with us. The rôle Dr. Everts gives civilization in explaining its effect on degenerates, its effort to keep life's stage as full of lag-guards as possible, is therefore but one of its parts.

It is most encouraging to see that degeneracy is at last winning due recognition as an element in the production of insanity; but it may be doubted whether the most ardent advocates of its influence in the production of morbid mental symptomatology will go so far as to think that insanity *per se* is a sign of anthropological degeneration. Inasmuch as *insanity* is but a general symptomatological designation which covers manifestations due to various morbid cerebral processes, it may still be maintained that all of us are obnoxious to "insanity" in one form or another.

CHARLES G. CHADDOCK, M.D.,

Asst. Sup't. Northern Asylum.

Traverse City, Mich., December 12, 1891.

To the Editor of the Journal of the American Medical Association:

Dear Sir:—In reading the report of the transactions of the American Electro-therapeutic Association, I find some errors which are calculated to mislead your readers. I therefore ask the privilege of correcting some which pertain to my remarks as reported in last week's issue, Dec. 5.

The stenographic report has no doubt been followed strictly, but the speakers have not been allowed to revise or correct the report of their remarks, which is to be deplored.

In the abstract of my paper, in describing the different coils, an error has occurred in dividing up the coil of No. 32 wire. It should read: Then another coil of No. 32 wire 800 yards long, tapped at 500 yards would give a coil of 800 yards, one of 500 yards and one of 300 yards.

In the second paragraph from the bottom of the first column, on page 887, it should read: When the coarse wire secondary coil only partially covers the primary there is less electro motive force to the current it furnishes than where it completely covers the primary, and when a high resistance is encountered, it is, of course, inappreciable as compared with the current from the fine wire secondary, which, when only partially exposed to the influence of the core, has a greater electro-motive force. But when the resistance is low the increased volume of the current from the coarse wire coil is more pronounced, because less electro-motive force is required for penetrating.

In the next paragraph the first sentence should end thus: *as the current has a greater electro motive force*, instead of, as you have more current.

The third paragraph on the last column of page 887 should read: Dr. Englemann, of St. Louis, has made some observations upon the action of this current which are

foreign to my experience. He claims that in recent injuries and venous engorgements a better effect is obtained from the current from the coarse wire coil than from that from the fine wire coil; that in these conditions the current from the fine wire coil will produce irritation. This may explain the apparently unfavorable effect of the current in the case related by Dr. Hayd. He, Dr. Hayd, did not know what injury had been produced by examinations or otherwise before the application of the current.

Other errors are noticeable which are not important, but show that the stenographer did not transcribe his notes easily, and the construction is clumsy.

Respectfully,

AUGUSTIN H. GOELET, M.D.

N. Y., Dec. 7, 1891.

MISCELLANY.

ASSOCIATION OF MILITARY SURGEONS OF THE NATIONAL GUARD OF THE UNITED STATES.—The second annual session of the Association of Military Surgeons of the National Guard of the United States will be held at St. Louis, April 19th, 20th and 21st, 1892. An interesting programme of addresses by prominent surgeons of the National Guard and the United States Army has been arranged, and a goodly number of scientific papers on military and accidental surgery will be read and discussed, and all matters pertaining to the health, usefulness and welfare of the civilian soldiers will receive attention.

The afternoon of one day will be set apart for an object lesson from the "Manual of Drill" by Hospital Corps of the United States Army, detailed for this purpose. This will be a very important as well as instructive feature of this session. The evenings will be given up to entertainments, receptions and banquets, which the medical profession and generous citizens of St. Louis have planned for their distinguished guests. The Committee of Arrangements have received the assurance that transportation will be satisfactorily reduced on all railroads and steamboats, to and from this meeting. The several hotels have promised a low and uniform rate, which will be announced at an early date. It is anticipated that not less than 500 surgeons and assistant surgeons of the National Guard of the United States will be in attendance, to all of whom the Committee of Arrangements extend a most cordial welcome.

EUST. CHANCELLOR,
Chairman Committee of Arrangements.

THE LOOFAH AS AN ASEPTIC SCRUBBING BRUSH.—The desire of surgeons to obtain a clean brush for scrubbing the skin before operations, in order to remove accumulations of epithelium and bacteria, makes a cheap article a desideratum.

I think that small pieces of the Egyptian loofah, which is found in all drug stores for use in the bath-room, meet the indications admirably. For a number of years I have used pieces of this material for cleansing the skin before operations. A single loofah costs about 10 cents, and is large enough to be cut into ten or a dozen pieces. After use these pieces may be thrown away, as the cost is rather less than a cent each.

This vegetable scrubbing brush, as it may be called, is of course of no value in cleansing a surgeon's nails, because it will not enter the subungual spaces as will the bristles of a brush.

I usually carry in my operating-case three or four pieces of loofah for scrubbing patients. It comes compressed like sponges, and a piece cut off before the loofah has been soaked in fluid can be carried in a small compass in an operating-case. For hospital use, pieces of loofah can be kept soaking in sublimate solution until used, and then thrown away, or soaked again, as the more expensive nail brushes are treated.—JOHN B. ROBERTS, M.D., in *Medical News*.

A VENEREAL CONGRESS.—A project is now under discussion by different boards of the Paris municipal government to establish an International Congress to consider questions connected with prostitution and the limitation of venereal diseases. It is proposed to hold the Congress in Paris, in 1893, and to invite medical men, lawyers, sanitary officials and political economists.—*Boston Med. and Surg. Journal*.

IN France the law provides that the person who summons a doctor thereby makes himself liable for the fee.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from November 28, 1891, to December 4, 1891.

Capt. Robert R. Ball, Asst. Surgeon U. S. A., leave of absence granted is extended one month.
Capt. Louis M. Maus, Asst. Surgeon U. S. A., is granted leave of absence for one month.
First Lieut. Paul Shillock, Asst. Surgeon U. S. A., is relieved from duty at Ft. Yates, N. D., and ordered to Ft. Grant, Ariz., for duty.
Capt. Arthur W. Taylor, Asst. Surgeon U. S. A., having been found incapacitated for active service by an Army Retiring Board, will proceed to his home.
First Lieut. William N. Suter, Asst. Surgeon U. S. A., is relieved from further duty at Ft. Grant, Ariz., and assigned to duty at Ft. Bowie, Ariz.
Capt. William O. Stephenson, Asst. Surgeon U. S. A., is relieved from duty at Columbus Bks., O., and will report in person to the commanding officer, Ft. Niagara, N. Y., for duty at that post.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending December 5, 1891.

Surgeon T. C. Heyl, placed on the Retired List December 3, 1891.
Surgeon W. H. Jones, promoted to Medical Inspector November 14, 1891.
P. A. Surgeon Frank Anderson, promoted to Surgeon November 14, 1891.
Asst. Surgeon N. J. Blackwood, from Navy Yard, League Island, Pa., and to the U. S. S. "Miantonah."
Asst. Surgeon Lewis Morris, ordered to the Navy Yard, League Island, Pa.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Three Weeks Ending November 28, 1891.

Surgeon John Vansant, leave of absence extended ten days. November 27, 1891.
Surgeon J. B. Hamilton, detailed for special duty. November 25, 1891.
Surgeon Fairfax Irwin, to proceed to Cape Charles Quarantine for duty. November 25, 1891.
P. A. Surgeon H. R. Carter, to proceed to Savannah, Ga., for temporary duty. November 19, 1891.
P. A. Surgeon C. E. Banks, to proceed to Boston, Mass., for special duty. November 9, 1891. To proceed to Washington, D. C., on special duty. November 24, 1891.
P. A. Surgeon P. C. Kalloch, relieved from duty at San Francisco, Cal.; ordered to Boston, Mass. November 20, 1891.
P. A. Surgeon J. H. White, to proceed to Harris Neck, Ga., for special duty. November 17, 1891.
P. A. Surgeon P. M. Carrington, to proceed to Harris Neck, Ga., for special duty. November 19, 1891.
P. A. Surgeon L. L. Williams, granted leave of absence for twenty-nine days. November 14, 1891.
P. A. Surgeon W. J. Pettus, relieved from duty at Cape Charles Quarantine; ordered to Buffalo, N. Y., for temporary duty. November 25, 1891.
P. A. Surgeon T. B. Perry, to rejoin station at Baltimore, Md. November 10, 1891.
Asst. Surgeon J. O. Cobb, granted leave of absence for twenty-one days. November 13, 1891.
Asst. Surgeon G. B. Young, to proceed to Memphis, Tenn., for temporary duty. November 13, 1891.

ORIGINAL ARTICLES.

VERTEBRAL SURGERY WITH REPORT OF THREE CASES, AND A NEW METHOD OF OPERATING IN THE DORSAL REGION.

Read before the Illinois State Medical Society, 1891.

BY F. C. SCHAEFER, M.D.,

SURGEON TO WESLEY HOSPITAL, PROFESSOR OF ANATOMY
CHICAGO MEDICAL COLLEGE.

Operations upon the spine are called for in cases of: 1. Traumatism; 2. Neoplasms; 3. Caries. It is my desire to occupy a few moments of your time by briefly reporting three cases of the third class, and giving the result of operations upon the cadaver, done with a view of ascertaining how to attack the diseased bodies of the vertebræ with the least degree of danger to, or disturbance of, the spinal cord in the dorsal region. Among the most troublesome cases the surgeon has to contend with, we may safely place caries of the vertebræ, and especially the tubercular variety. During the past two years it has fallen to my lot to treat a number of these, three of which I will report at the present time as germane to the topic, viz.: "Operations upon the spine for caries of the bodies of the vertebræ."

History. Case 1.—Miss C. J., aged 29 years. Admitted into Wesley Hospital, Nov. 13, 1889; well nourished. Three years ago was treated for rheumatic fever. Has had pain in her back over lower dorsal region from that time to the present. Has always had a weak back. Two months ago the pain began to grow worse. Three weeks later she noticed a slight swelling behind the pelvis under the crest of the ilium.

Examination.—There is a large swelling on the gluteal (right) region, hemispherical in form, about $5\frac{1}{2}$ inches in diameter at its base. There is also another swelling of considerable size in the right iliac region. Upon palpation fluctuation is elicited in both tumors and a communicating wave can be distinctly felt projected from one tumor into the other over the crest of the ilium. She cannot sit erect. When she makes the effort it gives her great pain in the back. Pressure upon the spinous processes of the tenth

and eleventh vertebræ (dorsal) makes her complain of great suffering in the corresponding portion of the spine. Feels most comfortable with her body bent forward and thighs placed upon the trunk. She occasionally has pain in the course of distribution of the branches of the anterior crural nerve. Can not walk without support, and then with great effort of will. Temperature 100° F., pulse, 84.

Diagnosis.—Caries of the body of the 10th or 11th dorsal vertebra, or both, with psoas abscess.

Treatment.—With antiseptic precautions I aspirated the gluteal abscess, in the presence of Drs. McNamara and Lorman, withdrawing fully a quart of tubercular fluid and immediately injected a preparation of iodoform with glycerine and alcohol, and closed the wound with sublimated gauze, sealed with collodion. For about one week she was much relieved of pain, but the abscess cavity gradually filled up and her temperature varied from 99° to $102\frac{1}{2}^{\circ}$ F., until December 27, when she seemed to be in a worse condition than when she entered the hospital. I now decided to drain the cavities, and if possible, attack the seat of disease. Made one incision above the crest of the ilium, over the interval between the latissimus dorsi and the external oblique muscles, the point through which the two abscess tumors communicated. There was a discharge of about a quart of tubercular fluid. Carried finger down into the pelvic abscess cavity; found it extended to the crural arch. Cured and washed it out with bichloride solution; treated gluteal abscess in the same manner and inserted drains. Next carried a curved uterine dressing forceps through the sinus behind psoas muscle to upper border of the first lumbar vertebra, cut down through the muscles at this point and carried a tube through from crest of ilium to the last rib; next enlarged opening under the last rib, and carried probe up in front of the transverse processes to the body of the tenth dorsal vertebra, and here struck dead bone, which I partially curetted with a small bent instrument, similar to Simms' uterine curette. It was, however, impossible to curette thoroughly, owing to the interference of the transverse processes. I succeeded in carrying a drainage tube into the body of the bone between the transverse process-

es of tenth and eleventh vertebræ, through which the pus discharged freely. In 24 hours temperature was 104° ; in 36 hours, $98\frac{1}{2}^{\circ}$. From December 27 to March 4, temperature fluctuated between $98\frac{1}{2}^{\circ}$ and 100° , averaging about $99\frac{1}{2}^{\circ}$. April 5 placed her in a Sayre jacket, which she wore four weeks, and during this time she walked about the hospital with ease. Temperature averaged 99° . June 8 renewed Sayre jacket. June 17 manifested lung symptoms, advised her to go into the country, hoping a change of air would do her good. Temperature 100° . The sinuses were all healed in two months after the operation, excepting the one going directly into the body of the tenth vertebra, which still discharged a little pus at times. Six months after her departure from the hospital she died of tuberculosis of the lungs. This patient was very comfortable for four months, from January 10 to June 1; almost entirely free from pain, and had perfect use of her limbs.

History. Case 2.—Miss H. W., aged 21 years. Entered Wesley Hospital March 26, 1890; considerably emaciated. Mother and father in good health. Sister died of consumption at the age of 22 years. About one year ago our patient began to feel pain in the back of her neck upon rising from bed, which became more and more severe, and in about two months' time extended to the left arm, which was soon paralyzed. She lost entire use of the arm. After another two months the arm began to improve, but her neck grew worse, and for one month she lost her voice, which, however, came back suddenly. Then her face began to swell and teeth decayed rapidly. Soon after restoration of voice she noticed a swelling in the left sub-occipital triangle, which constantly increased in size until it had filled the entire posterior triangle. All this time patient suffered excruciating pain, day and night, at the back of head and neck; also over left shoulder, left arm and ulnar side of corresponding hand. She also experienced difficulty in swallowing. I found a large, hard tumor situated at about the middle portion of the left side of the neck pressing the sterno-mastoid muscle outwards and forwards. The common, internal and external carotid arteries appeared to be pressed forwards in front of the tumor. The neck was slightly flexed to opposite side. With index finger inserted through the mouth, a convex projecting tumor could be felt encroaching upon the lumen of the left half of the pharynx. Retaining finger in pharynx and placing the other hand over the outside of the tumor in the neck I could feel that the pharyngeal growth corresponded to the cervical. No fluctuation. The tumor seemed as dense as bone, and as large as a medium sized orange. It was variously diagnosed by different physicians. One called it a cancer; another fibroma. I concluded

that it was either an osteo-sarcoma or abscess from caries of a cervical vertebræ. The extreme hardness being the only doubtful feature with reference to the latter. March 31 I concluded to operate, with the assistance of Drs. Danforth and Greene. Made a large incision behind the sterno-mastoid muscle, avoiding the branches of the cervical plexus, which were carefully drawn aside as the dissection progressed. Immediately after cutting through the deep layer of the cervical fascia fluctuation was apparent. I opened the wall of the abscess. There was a tremendous gush of blood, which was soon followed by cheesy matter. The blood, however, continued to well up at a great rate. I quickly dipped my finger into the cavity and found very large excavation in the body of the 4th cervical vertebra, in fact, there seemed very little left of the bone. Cured the walls of the cavity and stopped hæmorrhage by packing the hole with strips of iodoform gauze, and placed patient on her back without pillow for head. On the third day took out packing and inserted drainage tube. She could not hold her head up, as the supports were gone. Her neck felt as if it was broken. Kept her bed about two weeks. The wound discharged a little four weeks. After the second week adjusted a jury mast to her head and back, which permitted her to walk about. All pains were gone excepting a local tenderness of the spine. Twenty-four hours after operation temperature ran up to 101° . It was normal four-fifths of the time from day of operation until her discharge, May 15, 1890. Three months ago her mother wrote me that her daughter had laid aside her jury mast, could hold her head erect, and was engaged about the house doing housework; was feeling well.

Case 3.—Mr. H., aged 35 years; horse-shoer. Admitted in Wesley Hospital January 28, 1891; American. Patient had inflammatory rheumatism when a child. Some years ago had typhoid fever. Has been quite well for many years preceding the present illness. One year ago last October he was bruised in the back by a refractory horse, has had slight backache ever since, in the sacral region. Last March he began having pain in the left hip and was treated for three or four months for sciatic rheumatism. In September a swelling on the hip was noticed and his doctor cut down upon it, finding tubercular fluid. There have been several attempts to find the origin of the discharge, none of which have been successful.

Examination.—Patient is quite emaciated, but says he has a good appetite. There are several large scars on his hip from previous incisions. There is also a triangular opening on the gluteal region, high up over the back of the ilium, which communicates by a sinus six inches long with one over the trochanter major. There is a free dis-

charge of pus from both of these wounds. Lungs in good condition. Bowels loose. He is too weak to sit up. Pulse 113. Temperature $101\frac{1}{2}^{\circ}$. Exploration of wounds reveals necrosis of trochanter major on its posterior border; quite an excavation exists here. Several sinuses are present, one extends directly through the thigh to its inner border behind adductor muscles, a second sinus leads up to the back of the ilium, and a third one communicates with the pelvic cavity. I passed a flexible uterine sound into the latter opening behind the tuberosity of the ilium, back of the rectum to the anterior surface of the sacrum, a distance of nine inches. The probe struck denuded bone on the anterior surface of the body of second sacral vertebra towards left side. The patient complained of great pain over the sacrum. His legs were strongly flexed. The psoas muscle of the diseased side was contracted.

Diagnosis.—Caries of the sacral body with secondary infection of trochanter. February 9, with assistance of Drs. Danforth, Sage and Miller I concluded to scrape the dead bone and drain the parts diseased. First cut down on trochanter and chiseled away the diseased tissue. Next made a vertical incision one and a half inches to the left of the spinous processes of the last lumbar vertebra, extended this incision into the back of the sacrum. This cut led me into the triangular space below the transverse process of the last lumbar vertebra, bounded below by the body of the sacrum, at its outer side by lumbosacral ligament, limited internally by the body of the last lumbar vertebra. Through this opening (two inches deep) I passed my finger and hooked it over the anterior surface of the sacrum into the pelvic cavity. With a bent probe reached the diseased bone, then introduced a bent curette with flexible handle and curetted as well as possible the sacral segment, which was necrosed, also lightly scraped the long sinus from below, and finding it impossible to carry a tube from the lower opening at the trochanter through pelvic cavity to the upper opening at the top of the pelvis, distance of ten inches, I concluded to make a sally by way of the great sciatic notch, half way between the two openings. I therefore cut through the gluteus maximus muscle to the upper border of the notch, and thrust a uterine sound, bent into a half circle, through this opening over the front of the sacrum and the promontory into the upper opening. As this opening was two inches deep, it was not possible to bring the sound to the surface, but, with the assistance of Dr. Danforth, a silk thread was fastened below the bulb of the sound and carried through the pelvis; a drainage tube was now attached to the lower end of the thread and drawn through, giving an excellent drain to the diseased bone. Another drainage tube was carried through the

thigh transversely behind trochanter and adductor muscles, and a third drain inserted for the trochanteric cavity. Twenty-four hours after operation his temperature was 99° . It fluctuated between normal and 102° , averaging about $99\frac{1}{2}^{\circ}$, until the day of his discharge, March 4, when it was normal. About ten days ago I received information that he was able to sit up, and the wounds were almost healed. There was still a little discharge from the trochanteric wound. In this case we examined the discharge at the hospital and found bacilli. The operation was undertaken with the hope of relieving, to some extent, the sufferings of our bed-ridden patient, and he certainly has been more comfortable since the operation, although ultimately I fear he will die of tuberculosis of the lungs.

The wounds in all cases were washed daily with bichloride, 1-5000, and sterilized water.

Spinal surgery has assumed an extraordinary degree of importance since the year 1887, following the report of Horsley's first operation for neoplasm, and since then a number of operations have been done for caries and traumatism. I hold that the necrosed bone of the spinal column should be treated upon the same principles as similar disease in other bones. In other words, when we are certain that suppuration exists, we ought to endeavor, if possible (providing that systemic conditions or other complications do not contra-indicate), to reach the seat of disease, remove all that we can of the dead tissue, and establish thorough drainage, for we know that a long continued suppuration with accompanying infiltrations of pathogenic fluid must soon undermine the vitality of our patient, and the paralysis accompanying many cases must be attributed to the inflammatory and suppurative processes, causing pressure upon the cord, rather than to the disease of the cord itself. (See paper of Dr. Geo. E. Elliot, *N. Y. Medical Journal*, June 2, 1888.) Grave as this operation ever must be, the experience of Drs. Morenau, Horsley, Albee, Lane, Duncan and White (*Annals of Surgery*, July, 1889), it seems to me, fully justify the procedure. These operators had ten cases of laminectomy (for caries) of the gravest kind. They report three recovered, four improved. One of complete paralysis of all four limbs recovered. One with incontinence of urine and feces, with complete sensory and motor paralysis, was also cured; a third one with paralysis of lower extremities recovered perfect motion of both legs. In two of these we are told that the laminae and spinous processes of the three successive vertebrae were excised—a most formidable operation. In view of these facts it appears to me that the old method of opening a psoas abscess a foot or more from the point of disease without attacking its *fons at origo* is unphilosophical, irrational and decidedly unsurgical. In cutting down up-

on the diseased body of a vertebra it would seem extremely desirable to avoid opening the spinal canal, to prevent injury to the cord, to avoid hæmorrhage into the canal, or even infiltration of septic matter, and this should be done before paralysis occurs, if possible, or at least as soon as an abscess appears with pressure symptoms. Such operative procedure is, however, not simple, as any surgeon who has made the attempt will attest, especially in the dorsal region. Laminectomy at this time of course defeats the object sought. With a view of ascertaining how to accomplish this most effectively and directly, I instituted a series of experiments upon the cadaver. In the cervical region it can usually be accomplished most readily by following up the sinus of the abscess cavity, or as has been done in the upper region of the pharynx, *via* mouth. In the lumbar region an incision over transverse processes through the superficial tissues and along the border of the multifidus spinæ muscles, $1\frac{1}{4}$ inches from the spinous processes, enables one to get behind the psoas muscle (as in case 1, reported), to the vertebral body. The sacral body can be reached as in case 3, *via* the triangle between the transverse process of the fifth lumbar vertebra and the base of the sacrum, also through the great sciatic notch; through or back of the rectum, or by trephining through the bone from behind. In the dorsal region between the transverse processes, but the space here is so narrow as to preclude the possibility of thorough treatment; I therefore incised the soft tissues, one inch from the spinous processes, uncovered and removed the transverse process of the diseased bone, or of the one just below it, and resected the head and neck of the corresponding rib. This permits a large finger to reach the postero-lateral angle of the diseased body, and gives room for the introduction of the curette, sharp spoon or forceps, and leaves a large space for drainage tube. Should it be desirable to carry the drainage tube through the column, a transverse process with end of the rib of the opposite side can also be removed, when it can readily be passed through. In doing this operation we must avoid the pleura, dorsal ganglia of the sympathetic, spinal nerves, and intercostal arteries. One can hardly avoid injuring the artery. The other tissues need not be damaged. Hæmorrhage can be controlled. The difficult part of the operation is in disarticulating the head of the rib, as it is deeply placed and firmly attached. To avoid injuring the pleura and the ganglia of the sympathetic, it is a good plan after sawing through (chiseling or cutting with bone forceps), the rib at its tuberosity, to strip off the periosteum in front of the neck and head of the rib. The transverse process I remove with chisel. The disarticulation of the rib can be done with scissors or knife, by

following the attachments of the ligaments about the neck and head of the rib. The operation is practicable, less formidable than laminectomy; the latter operation involves more cutting. The spinal supports are not so much weakened, and the spinal canal not opened, unless the back portion of the vertebral body is destroyed. Even then the posterior common ligament may protect the canal. Of course it is to be understood that the operation is not intended to take the place of laminectomy in cases of great angular curvature, but to be resorted to before the disease has produced any great deformity, as soon as an abscess has been discovered.

COMPLICATIONS DURING AND FOLLOWING ABDOMINAL OPERATIONS.

BY RUFUS B. HALL, M.D.,
OF CINCINNATI, O.

Abdominal and pelvic surgery to-day is practiced by as restless and ambitious a throng as ever fought for fame upon the battlefield. There is probably not a State in the Union which cannot produce at least one man from each county, who has made one or more abdominal sections in the past few years. In many instances the welfare of the patient is only a secondary consideration to them. The prevalence of the mistaken idea that intra-abdominal and pelvic surgery is an exceedingly easy procedure, and the desire for local fame is what induces the large per cent. of these men to undertake the work. But after they have had a few deaths on account of unlooked-for complications, they have learned that opening the abdomen and making the necessary operations is not always easy, as has been so frequently stated by abdominal surgeons. Not a few of these men, to my knowledge, have very wisely said, no more abdominal surgery for them. It is easy in many cases, after special training in all of the technique of abdominal and pelvic surgery, but most difficult without this.

These are trying times for men engaged in this special work. They have their position to sustain and their advancement to make against the many difficulties incident to the work, as well as against the failures of those who insist upon opening the abdomen because it is easy. We all know an uncomplicated ovariectomy is one of the easiest of the capital operations; yet we must admit that it is a serious one, to be carefully performed after careful consideration. We are to remember, that very frequently that which appeared to be a simple and easy operation, may, and not infrequently does, terminate in the most complicated condition, and the complications must be carefully overcome if we hope or expect to save the life of the patient. The removal of the tumor in many instances is the least part of the operation; and in these complications arising after the

operation, is where the man who has had ample training will save the life of the patient, while one who sees the complications for the first time, will probably have a death follow. The careful attention to every minute detail which alone can bring success to the operation, is only attained by long and careful training; that training which is obtained by an apprenticeship for many months with different operators; without which no man should undertake abdominal and pelvic surgery with the mistaken idea that it is an easy operation, and one devoid of serious risk. So long as the craze "to open the abdomen because it is easy" exists, the end must be disappointment to the operator and complaint by the profession. The sooner the men engaged in this special work come to the front with a report of their complicated cases, illustrating complications during the operation, and those immediately following it, and show that no man can be at all certain as to the gravity and extent of the complications to be met with in any given case, or what complications may follow the operation, the better for humanity and the profession at large. No man has a moral or legal right to open a patient's abdomen unless he is prepared for any emergency which might occur, and is himself competent to deal with the conditions found, on the spur of the moment and in a surgical manner; unless the exigencies of the case are such that the patient would be in greater danger from a few hours' delay than is ordinarily encountered from the inexperienced operator. A knowledge of the accidents that may happen is one of the best means of avoiding them, and this knowledge can only be attained by an apprenticeship extending over a long period of time, or at a great sacrifice to human life, if the work is prosecuted without preliminary training. It is now conceded by all that the success following pelvic and abdominal operations are measured by the ability of the operator to overcome the many complications met with in each individual case. It is also conceded that in the most carefully performed operations by the most experienced operator, there not infrequently arises at the time of the operation, or within a few hours or days, complications of the most grave character, which menace the life of the patient and not infrequently cause their death. When these complications come to the inexperienced, the patient is usually lost. The accidents and complications must, of course, vary according to the organ dealt with, or the nature of the operation. Frequently the abdominal cavity is opened with a view of making a diagnosis, and doing upon the spur of the moment that which is there revealed. We may have some idea of what we may encounter, yet we are frequently treated to extraordinary surprises; as illustrated in a case which I operated upon in September, 1889, in which an exploration was

made to clear up the diagnosis in an obscure kidney case in which the symptoms of stone were not well defined, and upon exploration there was found an irregular shaped stone impacted in the ureter some three inches below the kidney, which was removed by a second incision in the loin, after overcoming many unlooked-for difficulties; yet the patient recovered. Some of the gravest complications during the operation are caused by separating adhesions. In any of these cases we may have hæmorrhage or intestinal rupture, or both. They are the most frequent in long-standing pelvic inflammations of gonorrhœal origin. In some of these cases the tissues are so friable that it is impossible to apply a ligature in the ordinary way, and the vessels must be ligated separately; or what is still more difficult, and which must be done in some cases, is to cobbler stitch the broad ligament, a procedure that I have been compelled to do in three different cases before the hæmorrhage could be controlled, without which the patient would have died on the table. In two of these cases the tube and ovary came away when an attempt was made to bring the specimen up to the incision preparatory to passing the ligature; in the other case, when the ligature was tightened, it cut its way through the tissue; in all of these cases the hæmorrhage was frightful. In each of them the incision was at once enlarged, the patient's hips elevated, hæmorrhage temporarily controlled by pressure of forceps, after which the entire broad ligament was stitched through, controlling the hæmorrhage, and the patients recovered. In many of these cases the intestine is denuded of peritoneum at the point where the adhesions were separated. If we carefully place a few stitches and strengthen these weak points—a procedure I invariably adopt in all deep lacerations—we will save not a few lives which would otherwise be lost. In some of these cases we will have intestinal rupture after the most carefully performed operations, which must be repaired at once. This accident I have had twice in the past year; one, with a rent an inch long, recovered without fæcal or other fistula; the other had a fæcal fistula for fourteen days, but the patient recovered. In the first case the bowel could be brought into the wound and repaired, which was done. In the second this could not be accomplished; therefore the edges of the rent could not be so accurately coapted deep down in the pelvis, and the result was not so satisfactory. Complications arising after operations must be dealt with in the same concise, determined manner as those encountered during the operation, if we expect to save our patient. The following case illustrates what can be done in the presence of grave complications by prompt interference: The patient was operated upon in December last for gonorrhœal pus tubes. Everything went well until the morning

of the fourth day. The drainage tube was out, bowels had been thoroughly moved, and I began to congratulate myself upon having an easy convalescence after such a dirty pus operation. The morning of the fourth day, however, the patient complained of pain in the left half of the pelvis. The pain grew gradually worse during the day; she developed some fever in the evening, and spent a restless night. At six A.M. the following morning, temperature 101, pulse 120, with a circumscribed painful point in the region of the left stump, of a throbbing, burning character. She grew rapidly worse until the evening of the sixth day after the operation, at which time she had a pulse 150, temperature 104.5. All day the patient had been restless, and at times quite delirious. Everything in the shape of drugs which promised anything had been tried without avail. She had no chill or sweats, yet I felt certain that she had an accumulation of pus in the left side of the pelvis, and decided to reopen and drain the abdomen. Without the use of an anæsthetic, I removed a few stitches at the lower end of the incision, tore the wound open, and introduced the finger into the cavity, and broke up adhesions until I found the left pedicle; upon withdrawing the finger, an ounce or two of pus was discharged. I introduced a piece of gauze, and applied a gauze and cotton dressing. The patient slept well during the night; was awake but twice for a short time. She made a rapid recovery. The temperature was never up to 101 after that time. She went home on the twenty-sixth day. I am certain this patient would have died in a few hours if the pus had not been evacuated. It is such a serious thing to reopen the abdomen after operations that no one feels like doing so as long as the patient has any chance of recovery without it. For this reason we may delay, between hope on one hand and dread on the other, until the patient has practically no chance at all on account of the delay before we fully make up our minds to reopen. The danger of delay, where it is necessary to reopen, is very forcibly illustrated by the result in the following case, operated upon in June, 1890, for sarcoma of the ovary, weighing four pounds. The pedicle was a thick, short one, and was ligated with difficulty. Patient did well until the third day, when, after giving a physic, she developed symptoms of intestinal obstruction, which grew worse every hour. It was thirty-six hours later before I gave up hope of overcoming the obstruction with salines and enemas. But by that time the patient was very much exhausted, yet, after a consultation with my friends, Drs. Reed and Ricketts, it was agreed that the only chance for recovery was to reopen the abdomen and relieve the obstruction. She was put upon the table under ether, a few stitches removed, and two fingers introduced into the cavity, which were

carried at once to the pedicle, and the obstruction found to be due to a coil of intestine adherent to the stump in such a manner as to cause complete obstruction when it was distended by gas. The intestine was separated without difficulty; the whole operation did not require fifteen minutes' time, and the patient's bowels moved before she could be placed in bed, yet she died three hours afterward from the shock. The case was lost because I did not have the courage of my convictions, to reopen the abdomen as soon as the diagnosis of obstruction was made, which was twenty-four hours before the cavity was opened.

The cases narrated in this paper are by no means all of those in which I have had complications, but selected to illustrate, in a measure, what every man will sooner or later encounter if he makes many abdominal operations. It is not necessary to relate more cases to show that abdominal operations are not always easy, and to illustrate complications which will certainly greatly embarrass the inexperienced operator. And when the complications occur, and they are not prepared to meet the emergency, the patient pays all too dearly for their inexperience by the forfeit of her life.

NEW METHOD OF INFLATING (CATHETERIZING) THE MIDDLE EAR.

BY J. M. BALL, M.D.,

PROF. OF OPHTHALMOLOGY, OTOTOLOGY AND RHINO-LARYNGOLOGY IN
KEOKUK MEDICAL COLLEGE, KEOKUK, IOWA.

The great importance of diseases of the middle ear, the serious and sometimes fatal consequences attending this class of cases, and the difficulty in applying therapeutic aid to an organ so deeply situated, are facts which are recognized by all enlightened medical men at the present day. In the therapeutics, as well as the diagnosis, of inflammations of the tympanic chamber, inflation occupies a prominent position. By inflation is meant the process by which air is driven through the Eustachian tube into the tympanum. There are various methods of accomplishing this result. Before proceeding further, I would ask your attention to a few historical facts.

HISTORY OF MIDDLE EAR INFLATION.

The Eustachian tube was first accurately described by Bartholomew Eustachius, professor of anatomy at Rome. He died in 1574, leaving posterity a series of splendid copper-plate engravings designed to illustrate the anatomy of the human body. These were his own handiwork, and, as time willed, were lost sight of for nearly a century and a half. When discovered, the Eustachian plates were presented by Pope Clement XI to his physician, Lancisi, who published them at Rome in 1714. In the work of Eusta-

chius the intrinsic muscles of the ear were first described.¹

Ten years before the publication of the book of Eustachius, Valsalva, as the best method for removing pus from the ear, recommended forcing air through the Eustachian tube, with the mouth and nose closed. This method is known as the "Valsalvan experiment."

Catheterism of the tube was first employed by Guyot, a postmaster of Versailles, who claimed to have cured an impairment of his own hearing by this means. Guyot introduced an instrument through the mouth, and probably reached the

name. Other methods have been described by Lucae and Gruber.

MODUS OPERANDI OF THE NEW METHOD.

It is my purpose, in this brief paper, to call attention to a method of using the Eustachian catheter which has given me most excellent results, and which, so far as my knowledge extends, has previously not been described. In order to avoid any possible controversy regarding priority in the use of the method to be described, I will here state that the idea was an original one to me, and that I have used the procedure almost daily for the past fourteen months. My method is based upon a new application of principles already known, and the use of instruments which already exist. In order to avoid any mistake, it may be well to repeat here, what is already implied by the title of this paper, that the procedure about to be described is an improved method of catheterization of the Eustachian tube. By the methods heretofore employed, the operator trusted entirely to the sense of touch to guide the catheter into position. By the method which I shall describe, *the operator can see, as well as feel, the instrument enter the orifice of the Eustachian tube.*

The method is as follows: The patient's nose is first sprayed with a cleansing solution, to remove all debris. A solution of cocaine is then sprayed over the lower nasal mucous membrane until anaesthesia is produced. The patient is then told to clear his throat of any mucus that may have accumulated. He is then given a rectangular tongue depressor, and told to hold it firmly in place, taking care not to push it backward so far as to cause retching. Artificial light is then to be concentrated upon the patient's mouth by a forehead mirror and White's palate retractor, which is self-retaining, is applied. The soft palate is drawn

forward with considerable firmness, and held in this position by means of a set-screw with which the instrument is provided. A hard-rubber Eustachian catheter is then passed into the nose on the side corresponding to the tube to be inflated, and allowed to remain. The next step is to take a rhinoscopic mirror in the left hand, warm it over the lamp or gas, and pass it into the upper pharynx behind the velum. It is at this point that the value of the palate retractor becomes apparent. It draws the palate forward and gives the operator

vicinity of the tube.² To him belongs the credit of originating the idea, while the merit of its practical employment belongs to Archibald Cleland, an English surgeon, who, in 1750, injected air and fluids through a silver probe-shaped tube, inserted through the nose.

In recent years Adam Politzer, of Vienna, has described the method of inflation which bears his

¹ Lancisi: Tabulae Anatomicae Clarissimi viri Bartholomaei Eustachii. Amstelredami, MDCCXII. Tab. xli. Fig. ix. x.
² Gruber: Diseases of the Ear, N. Y., 1891.

sufficient room in which to manipulate the mirror, which brings into view all the landmarks in this region—the septum, the choanæ, the superior, middle and inferior turbinated bodies, the fossa of Rosenmüller, and the orifice of the Eustachian tube. The last named is the objective point.

The mirror still being in the left hand, and the patient holding the tongue-depressor, the operator grasps the catheter between the thumb, index and middle fingers of the right hand, and passes the instrument directly into the orifice of the Eustachian tube. *Every step of the operation is visible in the rhinoscopic mirror.* The mirror is then quickly withdrawn, the hands are changed so that the catheter will be held by the left hand, while the inflation is completed by an ordinary air-bag held in the right palm. Finally, the catheter is withdrawn, the palate-retractor removed, and the operation is over. The whole manipulation can be done in less time than it takes to describe it.

To bring the pharyngeal openings of the Eustachian tubes well into view, it is advisable to use a mirror which is set at an obtuse angle with the stem, and to hold it as much as possible in a position facing the tubes. It is not possible, in all cases, to see all of the landmarks at the same time, consequently the mirror must be turned from side to side until the parts desired can be brought to view. The Eustachian orifice can be recognized as a pit, or depression, located external to the lower turbinated body. In the normal state, the mucous membrane at the entrance to the tube is paler than that in its vicinity, which is of a deep red color. As seen in the rhinoscopic mirror, the relation of the different parts is, of course, altered, those situated behind seeming to be in front, and *vice versa*. Thus the cartilaginous prominence of the posterior wall of the tube seems to be in front, and the anterior membranous wall with the salpingo-palatine fold is seen behind. So, also, the long diameter of the pharyngeal opening of the tube is, in reality, directed downwards and backwards, though in the mirror its direction seems to be downwards and forwards. Rosenmüller's fossa, again, which is behind the protuberant lip of the mouth of the tube, seems to be in front of it, appearing as a curved dark space.

There are very few patients in whom, on account of the excitability of the pharyngeal muscles, it will be impossible to carry out this method of inflation at the first sitting. In such cases it is sometimes necessary to apply a swab, soaked with cocaine, to the faucial pillars. After two or three sittings, the mucous membrane becomes accustomed to the contact of instruments, and the treatment can be carried out. In a few rare cases of pharyngeal spasm it will be necessary to use considerable force in drawing the

palate forward, but after two or three minutes the muscles give up the unequal contest and remain quiescent. The activity of the salivary and buccal glands, in pouring out an abundant thick secretion, may interfere with the view of the parts in the mirror. In such cases, either the operator should cleanse the throat with a swab of cotton held in an ordinary sponge-holder, or the patient should eject the saliva in the ordinary way. Most patients will have no trouble in clearing the throat, even when the palate-retractor is in place.

ADVANTAGES OF THE WRITER'S METHOD OF INFLATION.

What are the advantages of this method of inflating the middle ear?

1. In the first place, the operator is absolutely certain that the instrument has entered the orifice of the Eustachian tube, and for this reason the method I have described is of the greatest value in cases where we wish to apply astringents to the tube, or dilate it by means of bougies.³ There can be no guess-work about the procedure, since its whole field is visible in the rhinoscopic mirror. The difficulties which attend the ordinary methods of catheterization are obviated. There is no more prodding in the dark, and verbose rules for the introduction of the catheter, such as are found in all modern works on otology, are unnecessary. Turnbull says:

"The rules laid down by authors for the manner of introducing the Eustachian catheter are very unsatisfactory. The position of the pharyngeal orifice of the tube differs, as can be demonstrated by a rhinoscopic examination, and therefore no one rule is of universal application."⁴

2. The operator can adapt his instrument to the case in hand. By this I mean that he can change the length of the curve of the catheter to suit each individual case. Of course, I now have in mind the hard rubber instrument, which can be given any desired form. I consider the metallic Eustachian catheter a barbarous and dangerous weapon. I have often found that a catheter, which could be used successfully to inflate the tubes of one patient, would not answer for the next; and I remember several patients in whom the required curvature was radically different for the two sides of the same individual.

3. In using my method, there is no danger of emphysema. The danger of tearing the mucous membrane in the vicinity of the tube, and forcing air beneath it, is recognized by the standard authors of the day. At least three cases are on record of a fatal result following the use of the catheter. Hartmann, of Berlin, says: "Alarm-

³ "Although the employment of bougies for dilating the tubes, to which the older aurists so frequently resorted, has almost been abandoned, they have recently been very highly recommended again by Urbantschitsch."—Hartmann, *Diseases of the Ear*, 1887.

⁴ Turnbull: *Clinical Manual of Diseases of the Ear*, 1888.

ing and even dangerous accidents may be caused by the catheter injuring the mucous membrane and inflating the subjacent and surrounding tissues with air." It is a well known fact that the roof of the tympanum, while always thin, is often incomplete. Hyrtl has described this condition *in extenso*, and has called attention to the contiguity of the dura mater and the mucous lining of the tympanum at such points. Gruber, as long ago as 1864, stated that forced inflation of the middle ear, in the condition just named, may actually induce sub-meningeal emphysema. In the hands of a skilful operator, the method of inflation which I have described cannot be followed by any such disastrous consequences.

WHAT CAN BE DONE IN CEREBRAL SURGERY? REMARKS BASED CHIEFLY UPON PERSONAL EXPERIENCE IN TWENTY-THREE CASES.

Read before the Kansas City Academy of Medicine, November 28, 1891.

BY EMORY LANPHEAR, M.D., PH.D.,

OF KANSAS CITY, MO.

SURGEON TO EAST SIDE FREE DISPENSARY; PROFESSOR OF ORTHOPÆDIC SURGERY IN THE UNIVERSITY MEDICAL COLLEGE.

To those unfamiliar with recent advances in surgery of the brain, my paper may be something of a surprise because of the radical changes which have occurred in this department of operative surgery within the past few years; in fact, I doubt not there are some who will contend that we are too aggressive—that we invade the cranium with too much impunity. But from a careful study of twenty-three cases upon which I have operated (a series of cases presenting two deaths and twenty-one recoveries), and a review of recent contributions to the literature of the subject, I firmly believe that we have not yet awakened to the possibilities in operative surgery of the nervous system. Bremer, of St. Louis, says: "Owing to the comparative safety afforded by asepsis, many more skulls are opened than the state of our knowledge of the brain, its physiology and pathology, warrant." Perhaps in its broadest sense this is correct, but the opposite position is equally tenable; in proportion to our knowledge of localizing symptoms, *not enough* skulls are opened—in appropriate diseases.

For what can we operate?

1. Meningeal hæmorrhage.
2. Cerebral hæmorrhage.
3. Tumors of bones, meninges or brain.
4. Cerebral abscess or thrombosis of lateral sinus.
5. Cephalalgia.
6. Epilepsy.
7. Insanity.
8. Tuberculosis.

9. Microcephalus.

Operation for gunshot wounds, fractures, etc., is foreign to this paper, it belonging to accidental surgery.

MENINGEAL HÆMORRHAGE.

Of the practicability and necessity of operation for meningeal hæmorrhage there can be no question; since Macewen, in 1879, opened²⁰ the skull of a boy and removed 2 ozs. of fluid and coagulated blood from beneath the dura in the lower part of the Rolandic fissure, with recovery, cases have been too numerous, and results too satisfactory to admit of discussion. By the term meningeal hæmorrhage I include hæmorrhage between the bone and dura mater, and bleeding into the subdural or subarachnoidal space. Usually this condition is the result of injury, so there is no doubt as to the diagnosis in most cases—the injury being most frequently a rupture of the middle meningeal artery or its anterior branch. The symptoms may occur rapidly, but more often they appear gradually, the bleeding taking place slowly, and continuing until either tension or coagulation closes the vessels, or fatal compression is induced. In a typical case the patient is stunned for some time, but gradually regains consciousness. After an interval of from a half hour to a day or two, symptoms of compression make their appearance. In such cases trephining is always indicated. If one meets a case of non-traumatic origin, the diagnosis rests between meningeal hæmorrhage and embolic or thrombotic softening—a distinction not always possible to make. In such an instance, the patient should be given the benefit of the doubt.

When the intracranial hæmorrhage is due to injury, the external wound indicates the site for operative procedures. If there be no external guide, dependence must be had upon localizing signs, the broad rule being always borne in mind that for hæmorrhage from the anterior branch of the middle meningeal artery, the point of selection (unless very strongly contraindicated), is $1\frac{1}{4}$ inches behind the external angular process; while for the posterior branch, the point is a little below the parietal eminence. As soon as a diagnosis of meningeal hæmorrhage is established, the surgeon should open the cranium under strictest asepticism, remove the clot, thoroughly irrigate with water of a temperature of 110° F., put in a catgut drain, sew the dura with finest catgut sutures, and close the external wound with proper drainage, dressing as any other wound. The drainage tube may be removed on the second or third day. Small strips of iodoform gauze may be employed for drainage if so desired; they have given satisfaction in several of my cases.

The last operation for meningeal hæmorrhage in this city was by Dr. J. W. Perkins.² A boy

received a blow over the anterior branch of the middle meningeal artery. Evidences of compression, including hemiplegia, came on in due time. Four hours later Dr. Perkins trephined, and found a clot considerably larger than an English walnut; this was removed, the bleeding vessel attended to, the wound irrigated and closed. Recovery was uninterrupted and complete.

CEREBRAL HÆMORRHAGE.

Under the head of cerebral hæmorrhage I include bleeding into the substance of the brain, or into the cavity of the ventricles. Until within a very short time, these cases have been believed to be beyond the pale of surgical interference. Indeed, Horsley, one of the boldest of cerebral operators, as late as July, 1890, advises³ tying the common carotid artery in every case of bad cerebral hæmorrhage seen within four hours after the attack; to the universal adoption of which I must protest, and I note that Krönlein, of Zurich, says⁴ it must be restricted in its general applicability. Osler, of Baltimore, also condemns⁵ any attempt at surgical correction of the trouble, except when of traumatic origin. In fact, the only authority (in the English language) that I can find encouraging operative measures, is Landon Carter Gray, of New York, who states:⁶ "In cases (other than ganglionic) thus far reported, the lesion has been in the external capsule, between the lenticular nucleus and the cortex. Alcohol, insanity and trauma are etiologically related to cortical and dural hæmorrhages, while syphilis, chronic Bright's disease and cardiac hypertrophy affect principally the basal and cerebral vessels. As regards the type known as ingravescent or progressive apoplexy, the author rather inclines to the trephine as a means of possible relief. This must be done before the blood breaks into the ventricles. To reach a hæmorrhage in these cases the best place to trephine, as Dana suggests, would be a little below and in front of the parietal eminence. To reach the internal capsule in its anterior and middle parts, he recommends that a point be located halfway between the anterior and posterior ends of the corpus striatum and the optic thalamus respectively." Almost every work explicitly advises against operation. Thus Starr, of New York, says:⁷ "It is in cortical or surface hæmorrhage only that operations can be done. If the clot be upon the external surface of the hemisphere, and produces symptoms of aphasia, hemiplegia or hemianopsia, it can be removed." The reason he assigns for objecting to operation in subcortical hæmorrhage is that "when a hæmorrhage has occurred within the hemisphere, lacerating the tracts and destroying tissue, operative interference is out of the question, for tissue once destroyed in the brain is not repaired by nature, and even were repair possible, the surgeon could

not reach and remove the clot without producing a further laceration of important cerebral structures, or serious cerebral hæmorrhage." To this I must enter a demurrer. In the first place, in cerebral hæmorrhage, the tissues are often simply *pushed apart*, without serious laceration of the tracts or destruction of tissue (except by pressure necrosis), so if the clot be removed early, permanent injury may be prevented. In the second place, the surgeon *may* cut the white matter of the brain to a very considerable extent, without pronounced harm resulting. I have many times freely incised the brain tissue without serious consequences, and in gunshot and other wounds extensive injury has often been noted with no particular symptoms arising; and in the third place, the surgeon can readily control any bleeding which he may cause—so upon the whole, I regard his position as not well taken.

In 1883 Macewen, in a case of extravasation of blood into the white substance of the motor tract, where the clot was located by the symptoms present, operated and removed the clot, with recovery of the patient. Since that time a few operations have been made. Lucas Champonnier not long since reported to the Académie de Médecine⁸ a case of trephining for cerebral hæmorrhage. A man, aged 53, had an attack of cerebral hæmorrhage, the focus of disturbance being localized at the middle part of the precentral convolution; upon operation the remains of an old clot were found and removed, and the hemiplegia and aphasia disappeared. Champonnier has been able to collect statistics of thirty such cases, all of which were non-traumatic in origin, with no deaths and no untoward occurrences. Encouraged by this success, in spite of the condemnation of authorities, I have operated once for cerebral hæmorrhage, not traumatic.

Case.—Dr. W. C. B., age 47, had a slight attack of cerebral hæmorrhage in the early part of 1891. I saw him at Carthage, Mo., October 10, 1891, in consultation with Dr. R. T. Scott. The following is the entry in my case book: "Patient had 'stroke of paralysis' about two weeks ago; had all the symptoms of cerebral hæmorrhage, has not entirely recovered consciousness since. Has right hemiplegia and complete aphasia; has been rapidly emaciating, has lately had paralysis of sphincters, dysphagia and fever (temperature 100° to 101° F.), strength rapidly failing, to an alarming degree past few days; indicates that he has terrible pain and tightness in head, with insomnia therefrom. At 3 P.M., assisted by Drs. Mathews, Scott, King and Schaffer, I opened the skull over motor and speech centres. No pulsation of dura. On opening dura found some softening of arm centres; enlarged fenestrum and examined speech centres; no evidence of clot there, but indications of severe pressure. Removed remnants of clot (subcortical)

and some of softened arm centre, irrigated with hot bichloride solution, 1 to 5,000, put in catgut drainage and closed. Duration, one hour and thirty-five minutes. Put to bed in good shape with little shock. Pulsation of brain returned (at opening in skull) after operation.

"October 11. Slept finely all night on morphine, gr. $\frac{1}{4}$, and atropine, gr. $\frac{1}{80}$. At 9 A.M. is feeling first rate, better than at any previous time, mind much improved, can say 'Oh yes!' quite distinctly, and can move foot to marked extent. At 4 P.M. dressed wound and removed drainage, applied large quantity of iodoform and put on permanent dressing."

The subsequent history is given by Dr. Scott thus: "Three hours after our redressing the wound the temperature dropped from 100.5° to 99.6°. On the following day (October 13), temp. 99°, pulse 110, stomach irritable; applied mustard, and ordered milk and limewater in small quantities frequently repeated. At 4 P.M. temp. 100.5°, pulse 110 and intermittent, patient restless. Gave sulphonal 55, in milk, repeated in two hours, also hydrargyri protiodid. gr. $\frac{1}{4}$ every two hours until bowels move. October 14, 9 A.M. Temp. normal, pulse 100 and regular, appetite good; can urinate without catheter. At 7 P.M., temp. normal, bowels acted freely from mercury. Having slept well the night before, sulphonal was repeated. October 15, condition improving. October 20, on removing dressings, found head as dry and clean as when first applied; wound healed by immediate union. Patient is able to sit up several hours each day, and is entirely free from headache he had prior to operation."

The patient came to Kansas City, 203 miles from Carthage, on October 30. The amount of improvement was so great as to actually shock me. And a letter written November 24, by Dr. Scott, says: "Dr. B. is still improving."

Comment is unnecessary.

BRAIN TUMOR.

Operation for brain tumor is certainly an inviting one, the result from the expectant plan being invariably fatal, generally within two years. The wonderful changes sometimes apparently wrought by internal medication are deceptive, but do not prolong life. In most instances the growth can be readily localized, and in a large proportion of cases it is within reach of the surgeon's knife. While it is probably true, as Agnew says,⁹ that "the results of operations for extirpation of brain tumors cannot be considered as particularly brilliant," from the few cases I have seen, and from the excellent results obtained by Macewen of Glasgow, Carson of St. Louis,¹⁰ as well as others, I must agree with the statement of Clarence Bartlett, of Philadelphia,¹¹ that "in the absence of any reliable cure of brain tumor, one is not justified in waiting long for re-

sults if the symptoms are such as to enable him to locate the lesion accurately." As to this question of location, M. Allen Starr¹² states that about one-third of all cases occur in the basal ganglia, internal capsule, corpora quadrigemina, crura, pons and medulla, and so are inoperable. Of the remaining two-thirds, a considerable percentage must be amenable to surgical treatment. Even though the tumor may not be found, a large trephine hole may afford much relief if the button be not replaced, as in a case reported by Fischer, of Breslau,¹³ and also in a case of double trephining by Koehler,¹² to relieve symptoms when localization was impossible, the only pronounced features being choked discs, deterioration of vision, headache and unsteady gait. One opening was made anteriorly in the frontal region, with some bulging of the dura, and one posteriorly just below the tentorium cerebelli, where a hernia cerebri formed, which was removed with a Volkmann's sharp spoon, and the wound closed. Union by first intention was secured. Four days after operation the congestion of the discs had entirely disappeared and sight had improved. Seven weeks after operation the general condition was much better, sight the same, gait steadier and headache gone.

If the tumor can be located, I believe it should be removed if possible, even though it give but temporary relief. Some cases have been certainly *cured*, and the cerebral functions, strange as it may seem, entirely restored, after removal of even very large intracranial growths. Thus in a report by H. H. Mudd, of St. Louis,¹⁴ an immense echinococcus mass was removed from the brain of a girl of 12 years, it being larger than a hen's egg and located in the motor region, reaching from the convexity to the lateral ventricle. After shelling out the tumor, the wound was treated in the usual manner, the hole, large as it was, closed up, and the motor disturbances cleared up, viz.: tremor and hemiparesis, accompanied by hemianopsia and choked discs. Bremer explains¹⁴ restoration after such colossal defect by the assumption "that the fibres of the corona radiata, in which the tumor laid, were not destroyed, but merely pushed asunder; that though perhaps the myeline sheaths of these fibres were atrophied by pressure, the more resisting axis cylinders had preserved their continuity, and that complete regeneration took place."

VARIETIES.

The great majority of brain tumors are either syphilitic or tubercular—occurring as gummata or caseous masses respectively, the latter chiefly in young subjects. Other forms of tumor—more rarely met—are osteomata, sarcomata, fibromata, gliomata, carcinomata and cysts. Tumors other than those mentioned (very rare) are cysts of the

arachnoid, hydatids, plexiform angio-sarcomata, endotheliomata, etc.

Gliomata.—These growths, if not very vascular, may be easily removed. They are almost always found in the gray matter. If thoroughly extirpated recurrence is not probable and all symptoms may disappear. Thus P. Postemski, of Rome, on May 24, exhibited to the Royal Medical Academy at Rome¹³ a case upon which he had successfully operated some months before; all of the symptoms were gone and the woman was (apparently) completely restored to health.

Fibromata.—Fibromata springs from the meninges, are therefore easily accessible and readily subjected to extirpation. In the few cases I have been able to discover in recent literature success has been the result invariably.

Carcinomata.—Carcinomata are not frequently met in the brain; they are attended with just as great danger of return after removal as in any other part of the body. They commonly have a mass of hyperæmic and softened brain matter around the morbid growth, but in spite of this may be cut away, the adjacent tissue being cleaned out with a cutting Paquelin cautery.

Cysts.—Cysts are comparatively rare. They can ordinarily be removed without difficulty, though in a case in the practice of Dr. John Punton, of this city, operated upon by myself, there was not sufficient integrity to the cyst wall to allow of removal had such been our intention; the cyst was simply opened and a drainage-tube inserted. Experience has shown that cysts opened and drained give almost as good results as cerebral abscess.

Gummata.—Of these Horsley remarks: "Cerebral gummata should be removed—iodide of potassium palliates but does not cure them"—a statement in which all who have studied the subject must concur. The assertion of Agnew¹ may be taken as especially applicable to this class of cases. "The triumph already achieved by the conjoined labors of the neurologist and surgeon may be the harbingers of still greater ones in the future."

Sarcomata.—Sarcomata found in the head are either spindle-celled or myeloid as to variety. They may spring from the diploë, widely separating the tables, and at last breaking through with much suffering, especially if the growth be directed inward. In most instances they develop in the dura mater; the question of extirpation in such cases is of vital importance and still undecided. They frequently perforate the cranium and spread beneath the scalp, in which instance there is usually a distinct pulsation in the mass, reducibility when small and a characteristic sharp opening in the skull. I believe excision to be the correct thing, as Mansell Moulin maintains;¹⁷ the only question which arises in my mind is as to justifiability in advanced cases. In-

creasing experience in cerebral operation and (especially) observation of several cases of extensive destruction of the dura in St. Margaret's hospital in this city (under Dr. Perkins) lead me to the conclusion that we may remove a much larger portion of the dura than we have been wont to believe. I have removed an area $2\frac{1}{2}$ by $3\frac{1}{2}$ inches without apparent ill effect so far as cerebation is concerned. If the scalp and periosteum be brought over the hole so as to completely close it the brain gets on very well—in certain parts at least. In view of which I am strongly of the opinion that operations for sarcomata might be successful in more cases than now reported were surgeons less saving of the dura; and even should permanent paralysis result from interfering with motor areas such a termination is far better than death from the neoplasm.

Osteomata.—Those concerning us in our study of cerebral surgery are of the inner table or diploë (enostoses). As a rule they are of slow growth and may be left alone; but if serious symptoms arise, as displacement of the eyeball by osteoma of the frontal sinus or indications of intracranial pressure, they must be removed. A case in point is as follows:

Case.—Dr. W. L. W., aged about 35, first came under my care in the summer of 1889. He was then afflicted with aphasia and hemiplegia, of supposed syphilitic origin. There was considerable improvement after he had taken several drachms of mercury (red iodide) and some three pounds of iodide of potassium, with faradism for the paralysis, and in the autumn of 1889 I accompanied him to his home in Fairport, N. Y., and gave him into the hands of the trusted family physician who continued the treatment. February 5, 1891, he made his appearance at my office, saying he had come from New York for the purpose of having craniectomy made. I therefore placed him in the hospital for operation. My record made at this time states that "aphasia has greatly improved; disposition has changed so that patient is irritable, irascible and emotional, crying and laughing on slightest provocation; at present there is partial paralysis of entire side and complete of forearm; complains of constant priapism and constipation. Seems to be almost an imbecile at times; at others is quite rational but very emotional. Most of time passes urine in bed unconsciously—always unless drawn with catheter; has peculiar spasm of throat at times. Is very vulgar and obscene in language and careless of personal habits." On February 24, assisted by Drs. Richard Callaghan and J. W. Kyger, I opened the head with mallet and gouge over supposed site of trouble, removing the large piece of skull here exhibited: the opening was a little too far back, as at the anterior part only the bone was found greatly thickened and eburnated

—in fact the bony tumor was so hard that my large Rongeur forceps were broken in attempting to remove the growth, and the ivory-like tissue had to be cut away with carpenter's chisel and another forceps. The opening thus made measured about $1\frac{1}{2}$ inches by 3 inches, or a little more.

appeared; emotional disturbances had ceased; but paralysis remained unchanged. He was advised to go to some watering place and to use electricity for the paralysis, but unfortunately while *en route* to Waukesha he took too large a dose of morphine, and abruptly ended the case history. I believe that he would ultimately have

Figure 1.

This osteomatous tumor was of somewhat irregular shape, but quite smooth upon its surface; the pressure was such as to cause much bulging of the brain into the opening before the mass was taken away.

recovered because the electro-muscular contractility was not entirely lost, though almost absent in the forearm.

Cerebellar tumors (presenting symptoms of vertigo, vomiting, tenderness over the occiput,

Examination of the brain gave negative results. The remnants of dura were sutured without drainage, but a small rubber tube was put through the scalp, and wound in the scalp and periosteum closed with catgut sutures. Patient was put to bed in good condition.

Next day patient was much brighter and called for urinal instead of wetting the bed; no fever; in the evening he went to closet for movement of bowels. On morning of second day patient insisted upon dressing and going about ward as before operation; this he did daily with no apparent harm. The drain was removed on the third day; wound healed nicely by primary union; there never was an untoward symptom.

About the first of April he was discharged; there was great improvement in mental condition; rectal and vesical troubles were gone; difficulty in talking and deglutition had entirely dis-

cerebellar ataxia and paralysis of the fourth nerve) have proven bad cases for removal. In a dispensary case which came under the joint treatment of Dr. F. B. Tiffany and myself, we made a diagnosis of tumor of the middle cerebellar peduncle of the left side; exploratory operation was offered and refused; death was sudden; the autopsy confirmed the accuracy of our diagnosis but showed that an operation would have been unsuccessful as the growth extended downward until it implicated the fourth ventricle.

ABSCESS.

Abscess of the brain, from a surgical standpoint, is more favorable than tumor. The rule now is to operate always—death is certain; relief is sure if operation be made early enough; the mortality is very slight—three out of seventeen

cases collected by Von Bergmann—as compared with 100 per cent. mortality without operation. This condition may be the result of traumatism even when the skin has not been injured nor the bone broken (Mansell Moulin). The suppuration may be either diffuse (acute cerebritis running on to suppuration and proving fatal within a few days) or circumscribed, the area of red softening growing more and more liquid in its center until it simply becomes a collection of pus. In this instance the pyogenic organisms are carried to the site of injury by the blood. The abscess might be due to impaction of pyogenic emboli from some distant focus of suppuration, as the lung, in which instance it would be located near some twig of the middle cerebral artery. In most instances it is traceable to suppuration near by, as from injury or disease of bone. Of the latter we see a typical case in abscess accompanying inflammation of the mastoid cells and in otitis media suppuration.

But, whatever the cause, as intracranial suppuration, if left to itself, is practically hopeless, the indications are always to open the skull, evacuate the pus, irrigate the abscess cavity and establish free drainage. So essential is this that when the dura is opened at the supposed seat of abscess and no pus is found, an aspirating needle may be thrust into the brain in all directions until the pus is located. I have often used a large needle in this way (even withdrawing some fluid from the ventricles) without apparent harm to the brain. Great care must be exercised not to practice this extensive exploratory work in those doubtful cases which, instead of being cerebral abscess, are thrombosis of the lateral sinus or pyæmia from middle ear disease—conditions which closely simulate abscess in their clinical picture. Here the mastoid antrum must be explored first and free communication established with the external auditory meatus; by thus doing many cases of incipient meningitis might be averted. But if no pus is found, exploratory trephining must be made either a half inch above and somewhat in front of the meatus (to explore the anterior surface of the petrous bone) or just behind the meatus and on the same level. It is best perhaps to first explore the orifice of the mastoid vein and if no evidence of thrombosis be found, to then make the opening in front, exposing the under surface of the temporo-sphenoidal lobe where the abscess is often located.

"If no abscess is found in the anterior operation either between the dura mater and the bone, or in the substance of the brain, and there is no evidence of thrombosis even when the mastoid vein is exposed, the periosteum and muscular attachments must be separated from the occipital bone beneath the superior curved line, and the lateral lobe of the cerebellum be explored. In many cases of cerebellar abscess, however, there

is sinus thrombosis as well, and there must always be some danger of one of the two being overlooked if the other is found. If extra-dural abscess or thrombosis of the lateral sinus are found, the jugular vein should at once be ligatured. The only hope lies in thoroughly cleaning out the clot and removing the whole focus of the disease."¹⁸

"Localization in this class of cases as a rule is not difficult when the history of suppuration of the middle ear has been established. The temporal lobe or the cerebellum on the same side with the ear disease are the usual seats of these abscesses."¹⁹ This rule should not be ignored even when localizing symptoms and history point to other regions as well, as in the case of Chas. D., to be presently mentioned.

Abscesses are quite often not single. Kidd reports²⁰ a case of double abscess; the trephine was used in the frontal region and pus evacuated from an abscess; the patient died on the fourth day and the post-mortem revealed a second and larger abscess in the temporo-sphenoidal lobe of the right side *without* (a rarity, indeed) disease of the petrous portion of the temporal bone; the cause of the frontal softening was the recent kick of a horse; that of the posterior abscess was unknown—it usually being due to caries and often existing for months or years. A case almost precisely similar was lately operated upon by myself.

Case.—Chas. D., age 32 years, patient of Drs. Kestler and Mosher, received a blow upon the right side of the head by a cable car on the night of Sept. 18, 1891. He was stunned for a little time but recovered and went about his business next morning, though his employer noticed that he acted strangely—"dazed" as he expressed it. This condition continued until about October 11, 1891, when he had to go to bed on account of the increasing headache, especially marked at the junction of occipital and parietal bones of the right side. He developed fever, had a severe general convulsion, repeated chills at irregular intervals, and finally became delirious and semi-comatose. I first saw him October 18, in consultation with the doctors, but as there appeared to be marked amelioration of the symptoms it was decided that an operation should be deferred. He soon became worse again and continued to decline until the 23d. At 2 P.M., the doctors determined to have the operation made and at 4 P.M., arrangements were completed; but at that hour patient was in profound collapse, pulse weak and intermittent, extremities cold, eyes strongly turned to the left and insensible to light. Operation was therefore again postponed, stimulants being used vigorously. At 9 o'clock, October 25, we again met, Drs. C. D. McDonald and E. W. Myers being also present.

Upon opening the skull (about one and one-

half inches behind and a little above the external meatus of the right side) the dura bulged prominently into the hole, and was entirely without pulsation. On turning back the dura a large area of softened brain tissue presented—not yet broken down into pus, there being only a little spot of complete fluidification; this was scooped away and the surrounding red softening curetted with a sharp spoon and touched with the Paquelin cautery. A needle was now thrust in two or three directions without finding pus, but indicating quite extensive softening; this was very apparent to the touch of the finger also. After irrigation a drainage tube was inserted and the usual dressings applied. There seemed to be a slight improvement that day in his mental condition, but he suffered considerably from shock. On the evening of October 27, we dressed the wound; upon opening it up about one and one-fourth ounces of pus and broken down brain matter escaped. Dressings were reapplied and patient made easy, but he continued to sink and died next morning from shock and exhaustion.

The autopsy showed another abscess, evidently of months' standing, in the left side, due to caries of the petrous bone. While this had existed for a long time, the only evidence, presented *ante mortem*, was a chronic discharge from the middle ear and an occasional sharp pain in the occipital region of the left side. Death, in my opinion, was due to the recent abscess for which operation was made, though the concussion producing it may have set up trouble at the old focal lesion. Sooner or later, however, the latter would undoubtedly have caused death if not recognized and emptied.

In connection with the subject of abscess, it is of interest to note that Orlow has reported²¹ the history of a woman, aged 27, who was affected by suppurating thrombosis of the lateral sinus, diagnosed by symptoms and successfully treated by trephining. Briggs (C. S.), of Nashville, has had a somewhat similar case; operation for sinus thrombosis is quite common in malarial disease.

CEPHALALGIA.

Although it may seem rash to advise opening the skull for a thing apparently so simple as headache, there are certain cases of cephalalgia which resist all therapeutic measures; where such prove persistent and intractable, trephining should not be forgotten. Keen has operated once for intense headache following a blow, with complete relief from pain. Agnew⁹ reports two cases of persistent headache not relieved by medical treatment, one cured and one improved. Martin, of Philadelphia, is quoted by Agnew as having had a cure following operation for headache. Horsley has operated four times with four

cures. Prewitt, of St. Louis, twice with like result, and a number of other operators have had similar success.

In one case of almost unbearable headache which came under my own care in 1890, trephining completely relieved the distress, and permanently. I believe Victor Horsley is correct in advising that trephining be done in all cases of headache which prove refractory to other measures. Especially is this true of localized headaches and also when the pain seems to be the result of injury.

INSANITY.

The suggestion to open the skull in insanity is not new, but its execution is recent. Burckhardt²² has detailed six cases of insanity with marked hallucinations, which he subjected to operative treatment. "In two cases he aimed to intersect the paths of association which he thinks transmit the impression coming from sensory parts and certain ideogenic areas of the brain. A portion of the frontal and parietal lobes, before and behind the ascending convolutions, were removed with very satisfactory results in one case, the other being still under treatment. In the other four cases the hallucinations were more or less acute, and in these cases the operator attacked the centers through whose injury sensory and motor aphasia are produced, and removed a part of the first temporal and third frontal on the left side, which appeared diseased, and with satisfactory results. It is possible that, with additional experience and a minute study of the pathological changes seen in the brain, the knife may be the means of restoring to reason many cases now considered incurable." But the question naturally arises: were or not these cures the result of the operation *per se*? Only further experimentation and careful observation can determine. It is in the first stage of general paresis that I shall look for beneficial results, for here we have a mental disease (so-called) which is dependent upon gross lesions. In insanities dependent upon intra-cranial growths, the indications are always to operate.

EPILEPSY.

The question as to the propriety of operating for epilepsy, traumatic or otherwise, has been much discussed. There certainly appears to be much to base hopes upon, but results have not been altogether satisfactory—in fact, while there have been some very brilliant cures, especially when due to trauma, no improvement has been secured in a large proportion of cases. Personally I have operated once—a dismal failure. But I am persuaded to try it again by reports such as that of Péan.²³ Patient for years suffered from inherited epilepsy, not traumatic; internal medication failed. There was no localizing symp-

tom save pain, but an operation was made at the seat of pain and an angioma removed from the meninges, and implicating the superior longitudinal sinus. Cure has been complete and unquestioned.

Victor Horsley is a strong advocate of trephining for epilepsy; but upon the other hand White, of Philadelphia, regards²⁴ improvement as only temporary, and dependent upon the mental impression, and Agnew positively states,²⁵ "traumatic epilepsy is practically incurable by surgical operation," though he admits there are cases on which internal medication exerts no controlling influence that may be with great propriety subjected to operation, and cites the 102 cases collected by Laurient²⁶ with 54 per cent. cured. But, he says—and too much emphasis cannot be laid upon it—it is not too much to assume that surgery is responsible for the great majority of traumatic epilepsies, because of poor treatment at the time of injury, the doctrine that depressed fractures of the skull without symptoms require no operative treatment being responsible for many unfortunate sequelæ. I quote his own words: "However small may be the depression which follows a fracture of the cranium, save in one or two localities, it will encroach enough upon the dural nerves to cause more or less irritation, which, though insignificant at first, and not at all recognizable to the consciousness of the patient, yet eventually that irritation will be propagated to the cortex and brain ganglia, until finally the paroxysmal explosion occurs. . . . Whenever, therefore, in my judgment, the profession can accept the doctrine that *all depressed fractures of the cranium, however slight may be the depression, and entirely irrespective of pressure symptoms, are proper subjects for trephining*, then will traumatic epilepsy largely disappear."

Jacksonian Epilepsy.—In cases of limited epilepsy, or whenever the convulsion invariably begins in the same muscle or group of muscles, exploratory trephining is surely indicated, though as yet cases are too few and results too unstudied to warrant any definite promise of success. Parkes, of Chicago, warmly recommended operation, and others have been equally enthusiastic.

TUBERCULAR MENINGITIS.

Here is a disease wholly incurable by any method thus far devised. Some months ago I wrote:²⁷ "It is not unlikely that the time will come when we will boldly open the skull and wash out the meningeal spaces in cases of tubercular meningitis, as we do the belly in tubercular peritonitis. The peculiar disappearance of the tubercular process in peritonitis treated by flushing the abdomen, leads to the inevitable conclusion that a similar result may be anticipated in the analogous condition, tubercular

meningitis, especially when complicated with hydrocephalus."

Scarcely a week had passed when I was called upon to operate. I immediately addressed letters to Profs. Senn, of Chicago, and Keen, of Philadelphia, asking if operation were justifiable. The one replied: "I would tap with a small trocar under strictest antiseptic precautions, and inject 2 drachms of a 10 per cent. iodoform-glycerine emulsion, and repeat as often as necessary"—practically the same treatment as had proven so successful in tuberculosis of joints; the other advocated opening the skull, tapping the ventricles, irrigation and drainage. But the patient died before receiving their replies, and I was probably spared the necessity of adding a third fatal case to my list. It does seem to me, however, that something may be done in a surgical way for these fatal cases.

MICROCEPHALUS.

Last year Lannelogue, of Paris, proposed an operation for the relief of idiocy dependent upon microcephalus, believing the deficient cerebral development to be the result of premature closure of the fontanelles and sutures. This operation, which he calls craniectomy, he has performed twenty-four times, with varying degrees of success. Keen has also operated—in one case with marked improvement—but he believes simple trephining will accomplish as much as the more formidable linear craniectomy. Wyeth, of New York, has done the linear operation four times with two deaths, and decided improvement in one case. Van Lennep, of Philadelphia,²⁸ has operated twice—one child died three days after operation, the other, a boy 5 years old, has improved slightly. McClintock, of Topeka,²⁹ has made one operation, with very decided improvement. Other men have operated without death, but it is too early to report as to success or failure.

Two cases have been operated upon in Kansas City: one by Dr. J. F. Binnie, and one by myself. Both children died from shock. The history of my operation is as follows:

Lydia H., age 11 years, patient of Dr. John Punton. Was hurt when about 18 months old by a fall; picked up in an unconscious state. It was found that the right knee was injured. Convulsions recurred for some time after the injury. Condition of knee grew worse. At age of 5 years had scarlet fever, causing otitis media of left side, which was cured after a few months. Though lame, she at 7 went to school and began to learn to read. Soon afterward she had a severe spasm, repeated at frequent intervals for twenty-four hours, and since that time convulsions have been more or less frequent—at first at quite long intervals, but gradually increasing in frequency and intensity, until the average is from

twelve to twenty each week. In 1888 she lost her speech, and has not spoken since; this was accompanied by hemiparesis of left side. In 1889 leg was amputated for tumor albus; since operation left ear has again discharged, but hearing in right ear is good. Case came under care of Dr. Punton one year ago, and was placed on large doses of bromides, which seemed to control the spasms at first, but they soon returned as bad as before. She was greatly emaciated, but upon discontinuance of the bromides, under tonics and forced feeding, has much improved physically.

I first saw the case October 18, 1891, and made the following note: "Patient well developed physically; head unusually small and unsymmetrical, occiput being very prominent, especially on right side, face blank and expressionless, eye bright, and of the peculiar staring and restless character so often noticed in microcephalic children, pupils much dilated. Discharge from left ear; speechless, pays very little attention to what is said or done, lies upon floor and plays idly (for hours, it is said), with little pieces of wood; passes urine and feces in diaper, apparently without notice, has to be fed—in fact, lives a purely vegetative life. Is said to be irritable and vicious, *i. e.*, liable to harm others if not watched. At times is said to be much brighter, but for weeks at a time will seem to be oblivious to surroundings. At such times is apt to have many convulsions."

November 1, 1891, assisted by Drs. Eggers and Punton, I opened the skull on the left side, over the Rolandic fissure and the speech centre. There was some bulging of the dura, and no impulse. Upon opening the meninges, suspecting a cyst, I pushed an aspirating needle 1 inch into the brain, and withdrew 6 drachms of serous fluid. The needle was followed down with a bistoury, a free opening made, and drainage established. The dura was brought together with one or two sutures, and the scalp closed with continuous suture, except at point of drainage. The scalp was then reflected from the right side, and a linear craniectomy made, the opening being $\frac{3}{4}$ inch wide and $4\frac{1}{2}$ inches long. The dura was opened to permit inspection of the motor areas. There was distinct cloudy infiltrate in the pia mater, with adhesions to the convolutions in the arm and leg centres. The opening was enlarged with Rongeur forceps, because of *extreme* tension over motor areas; the adhesions were broken up, wound irrigated, dura closed, drainage tube to dura, and scalp closed. Duration of operation, one hour and forty minutes.

Patient was put to bed with profound shock, from which she never rallied. Upon recovering from the anæsthetic, there was a look of intelligence and brightness about the face that made the friends exclaim, "That change is enough to justify any operation." But in spite of vigorous

measures, she died at the end of forty hours.

Autopsy.—Nov. 4, 1891. Post-mortem examination held fifteen hours after death. Present: Drs. John Punton, J. T. Eggers, J. N. Jackson and Emory Lanphear. Rigor mortis well marked. Wounds in good condition. Upon removing calvaria pachymeningitis of long standing well marked everywhere. Right brain much smaller than left, and whole far smaller than normal; brain paler than natural. Sinuses empty, but vessels of pia much injected. Chronic inflammation of pia extensive. Dissection of brain revealed a cyst a little larger than a pigeon's egg in the speech convolutions a half inch below the surface, and encroaching upon the second frontal convolution. It was surrounded by a somewhat softened condition of the white substance, and walls of cyst were very thin. Frontal gyri not well developed.

Here was a case that promised something, and I am sure, had life been preserved, that there would have been some improvement, although speech could probably have never been restored; though what the developmental process might have brought forth is problematical.

I certainly cannot agree with Bremer that linear craniectomy for microcephalus is a bad operation. Of course, where there is a primary lack of cerebral development, closure of sutures being secondary, nothing can be expected from surgery; but there can be absolutely no doubt that some cases of defective mental development are secondary to premature closure of the skull, and in such craniectomy is certainly not only justifiable, but promises success in at least a moderate percentage of cases. So far as I can learn, the primary mortality is about 11 per cent.

METHOD OF OPERATION.

Whenever possible, the head is shaved on the day before operation, and an antiseptic dressing applied after careful scrubbing with soap and water. When the patient is anæsthetized (chloroform *always* being employed, because of contracting the cerebral vessels, and less liable to cause vomiting), the scalp is thoroughly scrubbed with brush, soap and water, dried, washed with ether, and then with bichloride solution, 1-1000. At this point, $\frac{1}{4}$ grain of morphine may advantageously be injected hypodermatically. A row of sutures are run "back stitch" around the field of operation to control bleeding from the scalp. A large flap is made, the cut being clean, and carried through the periosteum; a silk suture may be run through this flap as it is reflected and given to an assistant to hold. The method of entering the skull varies according to the habit and skill of the operator. Personally, I prefer the Galt trephine for fractures and the like, but for extensive openings I use the gouge, Rongeur and mallet and chisel. In twenty-three

operations I have never seen any bad effect follow their use, unless it be in the last case reported. Too heavy blows may, of course, produce shock, as Agnew has pointed out, but, by not too vertical position, and with gentle taps, the skull may be opened far more safely than with the trephine. If the primary opening is found to be too small, it may be enlarged with the Rongeur. If one desires to replace the chips, they are put in a mild bichloride solution of a temperature of 105° F., and when ready, are put back upon the dura in a kind of mosaic; these will grow to their place again, as practiced by Macewen, Adamkiewicz, and others; or we may fill the cavity with decalcified bone chips, after the manner of Senn, or even transplant from the goose, as in Jaksch's celebrated case. But I cannot see any special advantage in this (except in cases of extensive traumatism, where a large part of the brain is exposed, or in operation for neoplasm), as in operative cases we usually wish to remove intracranial pressure; besides, the opening is so promptly and satisfactorily filled with fibrous tissue that it is useless trouble, and the pieces may act as a foreign body.

The incision through the dura may be crucial or preferably made to follow the line of incision through the bone about one eighth of an inch from the margin, and extending three fourths around the circumference. The meningeal arteries may be caught with forceps and tied with fine gut, as anywhere else in the body. Hæmorrhage was formally greatly feared. Indeed, four years ago, when I accidentally cut the superior longitudinal sinus, I did not know how to control the bleeding, so I clasped it and the bone in a pair of forceps, and left the latter *in situ* for four days—with recovery; it was a case of gunshot wound, and not included in this list of cases. But now we have learned that the sinus can sometimes be tied, and if not, hæmorrhage can be checked by packing with iodoform gauze. Even in rupture of the lateral sinus this expedient has repeatedly proven efficient. For tying vessels of the meninges and brain, I employ juniper-oil gut, carefully prepared and softened. Bleeding from the diploë gave me much trouble in my earlier operations, and the use of wax, etc., was unsatisfactory and unscientific; now I simply punch the bleeding points with the handle of some convenient instrument, or even crush the bone if necessary. For small vessels in the substance of the brain, hot water irrigation usually suffices; but if persistent, they may be touched with the tip of a Paquelin cautery, or the wound packed with iodoform gauze. As the arteries which supply the brain itself are terminal, every vessel should be scrupulously maintained if possible; many times, as Horsley has shown, they can be lifted out of the sulci and preserved.

Hot water (115° F.), previously boiled, should be at hand to check bleeding, and, furthermore, for the purpose of douching the wound and head when symptoms of collapse appear. It has a wonderful effect in restoring the pulse and preventing shock.

In operating for tumor, if the growth does not present by simple inspection, palpation may detect it, and if not, the cortical substance may be cut through and the incision carried into the white substance. Such incision must be vertical, and directed into the corona radiata, avoiding, when possible, injury to other fibres, especially those going to the internal capsule. The gap in the brain caused by the removal of a tumor rapidly fills by eversion of the cut corona radiata and by granulation tissue, if large.

When the work has been done, the wound is carefully irrigated, and the flap of dura turned back into place. I always suture the dura with finest catgut, unless there be some strong contraindication. Few cases require a drain through the dura. A few strands of gut or a small drainage tube may be placed under the scalp, iodoform dusted in, the scalp sewed, and the wound dressed as any simple cut.

Shock is one of the great drawbacks to cerebral operations. In one of my two fatal cases, death undoubtedly occurred from this cause. Whenever possible, the patient should have a rest in bed for a few days before operation (unless very robust), with stimulants and forced feeding. At the time of operation, Champonierre advises one-tenth of a grain of sulphate of strychnine hypodermatically after the patient is under the influence of the anæsthetic. After the operation, the head must be kept low, the body very warm, and the usual remedies for shock employed (alcohol, digitalis). The after-treatment is the same as that of any other capital operation.

SOCIETY PROCEEDINGS.

Medical and Chirurgical State Faculty of Maryland.

Semi-annual Meeting, held at Rockville, Md., November 17 and 18, 1891.

President, Dr. Wm. H. Welch; Secretaries, Drs. Robert T. Wilson and William B. Canfield.

TUESDAY, NOVEMBER 17—FIRST DAY.

The meeting was called to order by the President, and Dr. E. E. Stonestreet, of Rockville, delivered the

ADDRESS OF WELCOME,

in which he regretted the illness of Dr. Maddox, and after recalling the early days of that part of the country, he welcomed the members of the Society in the name of the Montgomery County Medical Society. Dr. Wm. H. Welch, the President, in reply, thanked the County Society for its hearty welcome, and said it was a special pleasure to accept their kind invitation, because it was given so heartily. It was the desire of the State Society to make it a representative body and include all the local societies. He was glad to see such a large number, and hoped they would all feel at liberty to enter into the discussion.

Dr. Wm. H. Welch then delivered the President's Address, on

THE BACILLUS COLI COMMUNIS; THE CONDITIONS OF ITS INVASION IN THE HUMAN BODY, AND ITS PATHOGENIC PROPERTIES.

He began by saying that it might be considered rather remote from the interests of practical medicine to consider this subject; its study might not help diagnosis or treatment, but it was of the greatest interest, and in this case he thought he had something new to communicate. The invasion into the circulation or system of the bacillus coli communis had been always regarded as unimportant, and this organism was supposed to have no pathogenic properties; but now we know it has. It has long been known that a great many different kinds of low forms of life are in the fæces, and it has been thought that it was hopeless to try to classify them. Dr. Woodward, of Washington, has studied them very carefully, and has shown that the great mass of the fæces consists principally of low forms of life. He did not classify the different species. It was not supposed that there were any bacterial flora there. We owe to Escherich, of Gratz, the knowledge of the fact that there are certain species of bacteria which have their habitat in the intestinal canal, and are found comparatively infrequently

elsewhere. Of these the most important, because the most commonly found, is the bacillus coli communis. In 1885 he made his first contribution on the subject, his studies being based on the examination of the stools of nursing infants. He found this bacillus predominating. It is described as a short rod with rounded ends, about one-fourth to one-half the diameter of a red blood corpuscle; it is plump as compared with the tubercle bacillus. It has very little characteristic in its form. It is like many organisms which we already know. The typhoid bacillus resembles it so closely in its form, that one would not be able by the appearance alone, to distinguish them, but they can be distinguished by culture media. It is feebly motile according to some, and non-motile according to others. It grows in various culture media, in bouillon, in gelatin, in agar-agar and in a roll culture, the colonies are seen very faintly with the naked eye. The method of study is familiar to all bacteriologists. A sterilized platinum needle is passed into the substance to be examined, and then put into the liquefied agar-agar; this is then rolled horizontally on a piece of ice until the medium is deposited in a thin film on the inside of the tube, which is put in the thermostat over night, and the result is these small colonies which you see here. Their growth and reaction may be also noticed in milk. Add litmus to the milk, and then inoculate it with the pure culture of the typhoid bacillus and of the bacillus coli communis, and in the former case the milk remains fluid, and in the latter case the milk is coagulated. It is important to know whether the bacillus coli communis has pathogenic properties or not. The answer to this is equally important, whether positive or negative. In typhoid fever, the trouble is we cannot find an animal susceptible to the typhoid bacillus. When an organism enters the body, it causes disease either by infection or by intoxication. Infection is when the organism multiplies in the body, and intoxication is when the organism emits a poison. The bacillus coli communis causes an infection, not an intoxication. In experiments on rabbits, he injected a pure culture of this organism, and the animals emaciated and died in two or three months. At the autopsy it looked as if death was caused by the organism getting into the gall bladder. The effect seems to be according to the amount inoculated. He came across this organism in a case of pancreatitis. The etiology of this disease, which Dr. Reginald Fitz, of Boston, had so thoroughly written up, is obscure. Cultures were made from this case. It is not a post-mortem organism. When found in the body, it is a sign that it got there after death. At the Johns Hopkins Hospital, the autopsies are made soon after death, and thus the danger of post-mortem organisms

is reduced to a minimum. The abdomen was opened, and a large flat knife, which had been heated in the flame, was laid on the pancreas, thus destroying all organisms that might be on the surface of that organ; then the sterilized platinum needle was plunged into the substance of that organ, and the æse brought up a little speck of substance, which was put into the culture medium. In the case just mentioned, in which the bacillus coli communis was found in pure culture, there was a diphtheritic-looking condition of the intestinal mucous membrane. The organism probably made its way through the diseased intestinal mucous membrane, and thus got to other organs. He had found it in no less than thirty-three of the 250 autopsies which he had performed at the Johns Hopkins Hospital. All of these had a lesion of the intestinal canal. All had dysentery and a diphtheritic looking condition of the large or small intestine. There were hæmorrhages, ecchymoses, typhoid ulcerations. The question to be asked is: "Is the invasion of this bacillus of practical interest or not; does it do harm?" There is no evidence that it does, but in some cases it seems to. He had had some cases at the hospital of dysentery caused by the *amœba coli*. In these cases, which were usually fatal, he had found with considerable constancy the bacillus coli communis. It may be a factor of some importance. There are cases in which the organisms do injury. He had seen several cases of peritonitis of late; this is a most common cause of perforation. The peritoneal fluid was examined, and it was found to be a pure culture of the bacillus coli communis. He had seen a number of cases in which this organism had caused an infection of the laparotomy wound. He had seen six cases in all. In a number of these cases there had been numerous adhesions. It caused fever, and prevented union by first intention. It also does harm in the secondary broncho pneumonias. It is caused by some lesion in the intestinal tract. Fraenkel found this a common cause of peritonitis in one-third of his cases. The streptococcus and staphylococcus were also found.

Dr. Ernest Black, of London, thought that more and more light was needed on the precise nature of the products of decomposition formed by the bacilli. He asked Dr. Welch what power the bacillus coli communis had to be decomposed and be absorbed by the healthy mucous membrane?

Dr. Welch replied that this organism is not known to produce injurious chemical substances. Lactic and acetic acids are produced in the fermentation of milk. We have very little work done on the subject, but he does not believe absorption takes place.

Dr. George J. Preston read a paper on

THE REST CURE, AND CASES TO WHICH IT IS APPLICABLE.

He referred to Hodge's experiments, and changes produced in nerve cells by stimulation, and the restoration of these cells by rest. Hence the rest cure has a physiological basis. The natural relief of pain is rest. The necessary things in a rest cure are, isolation, rest, forced feeding and artificial exercise. Isolation should be used with bad cases. No one but the doctor and nurse should see the patient. She should be removed from home, and should have no communication with her family or friends. The diet should be regulated with great care; baths, friction and massage should be used where indicated. Milk should form a very large part of her nourishment. Electricity should be used, particularly the faradic current; also cold sponging and cold spinal douches. To what class of cases this is applicable, it is hard to say. There is a distinctive and easily recognizable class of cases to which this treatment applies.

Dr. T. A. Ashby, of Baltimore, said that the principles of treatment as laid down by Dr. Preston were important both to medical and surgical cases. He had had a number of cases in his own practice, where the rest treatment had been of incalculable benefit. He thought the ovaries were removed too often. Patients do much better when removed to a hospital, out of the reach of sympathizing friends. He agreed with Dr. Preston when he said that the surgeon might just as well remove the testicles for seminal emissions, as remove the ovaries of a neurasthenic.

Dr. Robert T. Wilson thanked Dr. Preston for his paper, and seconded what he had said, because he had had the same kind of experience in his own practice. He then related a case illustrative of this point.

Dr. Roger Brooke, of Oakdale, was very glad to hear the paper, and thought such work was productive of much good.

Dr. Black thought that forced feeding was of the greatest importance, and advocated especially peptonized enemata. There are many cases in which the patient, even with the most perfect rest, will not show improvement until they are put on forced feeding.

Dr. Welch said that the work of Hodge was decisive. The prolonged irritation of a nerve causes a change in its cells. This shows that a prolonged and continued functional disturbance may cause an organic disease. Thus Hodge found that prolonged cases of neuralgia will cause an organic disease of the nerve, and Thoma showed that the blood vessels in the neighborhood of this irritated nerve underwent a hypertrophy of their walls. Dr. Putnam, of Boston, has shown that organic disease of the nerves will follow a reflex irritation of that nerve. He was

susceptible on this point at first, but now he believed it.

Dr. Edward Anderson, of Rockville, showed an old medical work published in the last century showing that antiseptic surgery was thought of at that early date. He also exhibited an old account book of his father's kept in pounds, shillings and pence, more than a hundred years ago in that county.

Dr. Anderson then read a paper on

TYPHOID FEVER.

This disease came from the same cause, whether lasting long or short, whether mild or severe. If mild it was sometimes called malaria, gastric fever, and in some cases it was called typho-malarial fever. These names should not exist. He would call it headache fever, for that symptom is never absent, although all the more commonly present symptoms may be absent. Typhoid fever is the scourge of Montgomery county. Rockville is the home of this disease. This should not be so, for except for man's intervention there is not a healthier place anywhere. But not a house on the main street that had not been visited by this disease, and nearly every family in the town had had some member suffer from the disease. In his experience it either killed in a few weeks or else it left the subject in a better condition than he was before. The town was situated on three streets, which ran parallel. During wet weather there was no danger, but as soon as the streets dried, which they did in a few hours after the rain ceased, the clayey dust carried the disease. The side streets were generally wet, hence there was not so much disease on them as on the main street. In one house he had seven cases in a short time and in another five. He quoted several cases, and gave his plans of treatment.

Dr. T. A. Ashby, of Baltimore, thought it was generally caused by drinking-water, and said it was only strange that we did not have more cases in the country than we do.

Dr. Preston said that the proof of the spread of this disease by drinking-water was the fact that there is comparatively little typhoid fever in the cities, and many cases that do occur are brought from the country. Milk is also a cause. A field fertilized by human dejecta may be the cause of spreading the disease. He had noticed that one year the cases were mild and the next year they were severe. This year they were very mild. The cases that were lost were those that applied for treatment too late, in the last stages of the disease, and had been walking about. He objected to milk as an article of diet in this disease. Not only was it a good culture-medium for the organisms, but on account of its casein it was very indigestible in this disease. He had a strong preference for egg white as a substitute.

Dr. Henry U. Onderdonk, of College of St. James, said he had had an opportunity to examine a large number of samples of water for physicians of the region, and he had found chlorides, nitrites, nitrates, and each sample was backed up by one or more cases of typhoid fever. In one case the water seemed to be pure, and yet there was the typhoid fever.

Dr. J. McP. Scott, of Hagerstown, said this was a subject always interesting. He thought it was doubtful that the disease came from certain soils. In Munich the disease disappeared with the improvement of the drainage. He thought there was no special plan of treatment, only the less the better.

The faculty then resolved itself into a convention and appointed Drs. T. A. Ashby, J. J. Preston, of Baltimore, J. McP. Scott, of Hagerstown, W. Frank Hines, of Chestertown, and Edward Anderson, of Rockville, a committee of five to confer with other committees to frame a proper law for the regulation of the practice of medicine in Maryland, to be presented to the next legislature.

Dr. Welch, in continuing the discussion on typhoid fever, thought it was important to study the cases that differed from the usual forms. Much harm had been done by the text books by their descriptions of this disease. There are cases without the usually noted symptoms and cases with them. The cases of constipated typhoid fever are by no means the most favorable. Some cases assume the disguise of Bright's disease. The continued fever seems to be the symptom most common to all types. Harm has been done by setting up the type of typho malarial. The two diseases may be combined, but not often. Such a term is used to cover up the ignorance of the physician. We have means of recognizing malaria by examining the blood. If the malarial organisms are present we have malaria, if they are absent then we have no malaria. Typhoid fever is a disease which the physician should have in mind whenever he is called to attend a case of continued fever. He then related a case of walking typhoid fever. The patient had simply complained of sore throat, and had gone nearly every day to his physician. One day, on leaving the office, he fell dead on the street. It is a tricky disease and may assume all sorts of disguises. It is a novel thing to hear the ground hypothesis advocated in this country at the present day. The drinking-water is so generally considered the cause, especially in the opinion of Americans and English, that the ground hypothesis is in the back ground. Pettenkofer, who is a hygienist in the strictest sense of the term, is the leader of the ground hypothesis, while the bacteriological school of Koch is a strong adherent to the drinking-water theory. Typhoid fever may originate in various ways.

It generally comes from drinking-water, but it may not be impossible for it to develop in the way Dr. Anderson has said. Uffelmann found that it lived in the earth a year. The typhoid bacillus does not form spores, but it is very resistant. It may be taken in with the dust. The ground hypothesis cannot be denied entirely. Uncooked food may possibly cause it. Impure water may infect without being drunk; it may contaminate the vessels in washing them. It is well known that milk will cause the disease. The bacillus does not get in from sewer gas, but families returning to a house that has been closed for a long time may get the disease from the fact that the water in the drain and water closet pipes has evaporated, and any dried matter in these pipes, containing, among other things, the typhoid bacillus, may be wafted into the house by backward currents of air and cause the disease. In such cases the place just left, usually a summer resort, is blamed. In Munich the introduction of good water had no effect, but improvement of the drainage caused the disease to disappear at once. In Hamburg the reverse was true. The typhoid bacillus is not choice in what it eats. It will grow on almost anything. The fact that this bacillus grows readily in milk is no reason why we should deprive our patients of milk. As the bacillus will grow on almost anything, we should have to starve our patients in order to protect them. Besides, it is not so much keeping the organism from getting into the body, as to keep the body strong enough to throw off attacks of the bacillus. There is no substance which contains as much nutritive matter as milk, and nothing is better than it in typhoid fever.

Dr. E. E. Stonestreet, of Rockville, said that he had always thought that water was at fault in typhoid fever, and mentioned several cases of his own. This paper was further discussed by Drs. C. L. G. Anderson, of Hagerstown, Hines, Ashby and others.

TUESDAY, NOVEMBER 18—SECOND DAY.

Dr. T. A. Ashby then read a paper on

APPENDICITIS IN THE FEMALE, WITH REPORT OF TWO CASES.

He thought that this trouble occurred frequently in the female when it was not recognized, because the pus escaped by the vagina or in other ways. He related two cases.

Dr. Welch said that he had had some little experience in this disease, and thought that Dr. Ashby had called our attention to a very interesting subject, one little investigated, and this paper should prove an incentive to further investigation. The reason it is supposed to be so much more common in the male than in the female is because statistics are not properly collected. This is difficult. Proportionately there

are more males than females in hospital, but like cancer of the stomach it is no more common in males than in females. There are special causative differences in the two sexes. One case which he had seen at the hospital was one of extra-uterine pregnancy. It was tubal. The diagnosis had not been made before she entered the hospital. The third week the sac ruptured into the peritoneal cavity and there was profuse hæmorrhage. The patient was better in a week. The diagnosis was made by withdrawing with a sterilized needle, a little fluid from the peritoneal cavity, and this fluid, which was blood, was found to be a pure culture of the bacillus coli communis. This showed a perforation of the intestinal canal, for how else could this organism have got in? The diagnosis was confirmed subsequently. This was the only thing about the case that led to a suspicion of appendicitis. An operation was decided on and laparotomy was performed. As soon as the peritoneal cavity was opened the blood spurted out seven inches high and three inches thick. The patient died almost at once. The autopsy showed an appendicitis and diffuse peritonitis. There had been a tubal pregnancy on the right side, which had ruptured. The diagnosis was made with the microscope. The appendix was adherent to the sac on the right side, and this is probable. It is probable that the appendix was ruptured in rupture of the sac. This is interesting, the diagnosis resting on the bacteriological examination, and the sudden death. The patient had shortly before had a hæmorrhage into the peritoneal cavity; the tension was excessive, which compressed all the viscera and the blood vessels. This is different from the collection of an ascitic fluid, because that is a gradual accumulation and the vessels have time to accustom themselves to the change. The volume of blood in this case was diminished by the hæmorrhage. The abdominal vessels can contain all the blood of the body, and in this operation, the pressure being suddenly let up, the blood was drawn from all other parts of the body by suction and the circulation could not be kept up. In these cases salt solution injected into the blood vessels does as much good as blood, and is not so dangerous. This patient died of "hæmorrhage into her own vessels."

A still more interesting case was that of a negro, aged about 21, married three years, had had two miscarriages, and developed during the last six months great pain and weakness in the back and side, and leucorrhœa. She was not incapacitated for work. She came into hospital. Examination showed that the cervix was low down and enlarged, os patulous. On the left side was a fluctuating mass as large as a lemon; on the right there was nothing. Diagnosis, pyosalpinx of the left side. Laparotomy was

performed and the left ovary and tube removed. The fimbriated extremity was obliterated, ovary not involved. On the right there was no pyosalpinx, but evidences of disease. The contents of the right Fallopian tube were muco-purulent. The vermiform appendix was adherent to the right tube. A culture made from the pus in the left tube was negative and sterile. This is the usual result, and it is surprising. These are gonorrhœal, and later on the organism disappears; still it does not grow in the usual culture media, so that when we find such a case where there is no growth, we consider it gonorrhœal. He made cultures from the right Fallopian tube and found small cultures; they were the streptococcus pyogenes, the most virulent of the pus-producing organisms. He thought this was a case where the inflamed vermiform appendix had set up by adhesion a salpingitis. This is another cause added to the list of causes of this trouble. The finding of the streptococcus makes the prognosis worse than if other forms were found. It is the organism of puerperal fever and septicæmia. This patient was isolated and a drainage tube was not inserted, as he considered it a source of danger. The temperature went up to 104°, and she died soon after the operation. The autopsy showed a duodenal ulcer, an unexpected complication. There may be a relation between the ulcer and this case; he had seen three others like it, but could not trace the connection.

Dr. Robert T. Wilson, of Baltimore, then read a paper on

LAPAROTOMY FOR REMOVAL OF A PURULENT TUMOR OF THE RIGHT OVARY.

This was not a suppurating cystoma of the ovary, but an abscess *per se*. The tumor was as large as an infant's head. He put on the clamp, cut it off, applied Monsel's solution, put back the stump, and closed up the wound with antiseptic precautions. In order to give good drainage, he put in a tube. He thought it was important, after such operations, either to put in a drainage tube or an iodoform-gauze tent. The patient made a good recovery.

Dr. Ashby said it was interesting because it showed the difficulty in diagnosing these cases. He had had several such cases, but in none was the ovary so large.

Dr. Welch said that abscess of the ovary was rare, as Dr. Wilson had said. He had seen a few cases, but none so large as this. Suppurating disorders are caused by microorganisms, and it is difficult for organisms to get into the ovarian structure. In pelvic peritonitis they do not have to penetrate. The tunica of the ovary is so thick that organisms do not readily penetrate it. The different tissues react more or less readily to the invasion of bacteria, but the stroma of the ovary is not prone to suppurate. He men-

tioned a case of ovarian abscess from abscess of the rectum, and recalled a case of genuine ovarian abscess. They are not so very uncommon, nor are they so common. It is not easy to tell what we have when the abscess gets as large as the one mentioned, and be sure that it is an abscess of the ovary. The ovary may be depressed and covered by the abscess.

Dr. Wilson emphasized the importance of putting in a drainage tube or an iodoform tent to facilitate the escape of the discharge. He also used a large quantity of boiled water to clean out the cavity, and left a little to prevent clotting of the blood.

Dr. Welch said it was very proper to use a drainage tube in this case, where there was little chance of getting union by first intention; but if there were a chance of union by primary intention, a drainage tube should not be inserted.

Dr. William B. Canfield, of Baltimore, then read a paper on

OCCUPATION AND DISEASE; WITH SPECIAL REFERENCE TO THE CONNECTION BETWEEN THE INHALATION OF DUST AND PULMONARY DISEASE.

The substance of this paper was to show the dangers of inhaling dust in mills, mines, factories and other closed places where dust is present in excessive amount. This dust is dangerous because of its amount, its poisonous nature, or because it may make a way in the lungs for the invasion of the bacillus tuberculosis and other organisms. He suggested proper ventilation and means to carry off the dust.

Dr. Preston said that the class of cases he had seen had been in stone-cutters. He thought the trouble persisted even after the work stopped. He related a case of inhalation from grinding drugs. It had both a mechanical and poisonous effect. This is important, particularly where manufacturing is going on. We should be servants of the public health. He had seen many cases of lead poisoning occurring in men employed in the same place of business. With much difficulty on his part, and with great reluctance on the part of the owners of the yard, he found that the powder used to polish the stone contained lead, and this was inhaled in polishing, and caused the lead symptoms.

Dr. Welch had seen cases of anthrax from the dust in handling hides and sheep skin. There were intestinal mycoses. He had seen cases of siderosis in Saxony. Dr. Canfield is right in saying that we must consider each kind of dust by itself. The bronchial glands form a filter, but the dust may be carried to other parts of the body. An emphysematous condition tends to let the dust get into the lungs more easily than normal.

Dr. Canfield said he wished to emphasize the

dangers of dust inhalation both on account of the mechanical effect of the dust, and also because the crystalline dust tends to make a way for the entrance of organisms. It was also well to note that cases of pulmonary tuberculosis contracted tended to recovery when the case was removed from the dust.

Dr. J. E. Michael, of Baltimore, read a paper entitled

A CASE ILLUSTRATING THE DIAGNOSIS OF EXTRA-UTERINE PREGNANCY, AND THE DIFFICULTY OF PRODUCING ABORTION.

He related the case of a woman, aged 22, unmarried, who had been treated for suppression of menses, first by drugs, later locally, in view of a muco-purulent discharge from the cervix. Local treatment in applications to the uterine cavity of Churchill's tincture. This was done fifteen times, the applicator having been passed $4\frac{1}{2}$ inches. Dr. Michael diagnosed pregnancy in a sharply anteflexed uterus. Natural labor proved the correctness of the diagnosis.

Dr. Stone, of Washington, in discussing extra-uterine pregnancy, said we should know more of the diagnosis of this condition. He related several cases, and asked where this pregnancy occurred. A rupture through the tube into the broad ligament was called an interstitial pregnancy.

Dr. Welch related a case of a couple who had been married fifteen years without children, when the wife became pregnant. It was supposed to be an ordinary labor, and everything went on well, when she was suddenly taken with pain, collapse, and symptoms of internal hæmorrhage. As she was the wife of a well-known physician, many were called in. She passed some material by the vagina, and some thought it was a case of miscarriage, while others (Thomas and Lusk) said it was extra-uterine pregnancy. As it was easy to see the chorionic villi under the microscope, Dr. Welch, who was at that time just beginning his pathological studies, examined it and found decidual matter, but no chorionic villi, thus proving that it was a case of extra-uterine pregnancy. This shows the practical use of the microscope.

Dr. Stone asked if it was usual for hæmorrhage to occur at the fourth month outside of the sac. After a foetus is two weeks or a month old, he did not know what caused a hæmorrhage, and from what artery it came. There was no rupture of the sac.

Dr. Welch said the rupture of the tubal sac was common. He had never seen such a case where hæmorrhage occurred and there was no rupture.

Dr. Winslow said he had had two cases fifteen years ago. Hæmorrhage is usually the result of rupture of the sac; as the child grows, the tube

is not large enough to receive it, and as it cannot expand, it ruptures. The foetus gets into the peritoneal cavity, and is soon absorbed and is not found. This is well known.

Dr. Michael said he had not expected the discussion to take this turn, but he was very glad of it. He related several cases, and said he thought the clinical aid was generally sufficiently clear without the aid of the microscope.

Dr. Welch said it was interesting to observe what a wide field the discussion on extra uterine pregnancy and hæmatocele took now from what it did fifteen years ago.

Dr. Michael asked if it was always a ruptured pregnancy, or were there other conditions that could produce it.

Dr. Welch thought that a very large percentage of pelvic hæmatoceles were cases of extra-uterine pregnancy.

Dr. A. K. Bond, of Baltimore, then read a paper on

NOTES ON THE USE OF CODEINE.

He had used it in gastric irritation by the mouth and rectum, in the early cough and sleeplessness of the aged and in phthisis. The advantages were there were no gastric disturbances, no constipation, no increase of dose necessary, no habit formed, in fact no interruption in the harmony of the system.

Dr. Canfield said he had used codeine principally in diseases of the respiratory tracts. He had found it better than morphia in some cases, but it was often not powerful enough in the last stages of phthisis, where it made no difference whether a habit was formed or not.

Dr. Stone asked if it produced diaphoresis.

Dr. Bond had not heard of it. He thought the necessity of increasing the dose of morphia was caused by the disordered digestion.

Dr. Edward Anderson said his objections to the use of morphia were the irritation of the skin. It dries up the secretions and causes indigestion, nausea the next day.

Dr. Robert T. Wilson had used codeine for twelve years, and was always much pleased with it.

Dr. Randolph Winslow, of Baltimore, read a paper entitled

A CASE OF ELEPHANTIASIS OF THE SCROTUM.

His father died of meningitis. His mother of phthisis, and he was the last of six children, who had all died of phthisis. About three years ago his scrotum began to enlarge and his penis was almost in it. His virile power was unimpaired. He had never lived in tropical countries. He was given the iodide of potash with no effect. The scrotum was excised and testicles saved. The result was good. This disease is rare in

this country. He could not find the filaria in his blood.

Dr. Welch had seen two cases, and in neither could he find the filaria. He does not think the elephantiasis of Baltimore is parasitic.

Dr. Charles E. Stone, of Rockville, then read a paper on the

EARLY DIAGNOSIS AND OPERATION IN OSTEO-SARCOMA OF THE LOWER BONES.

He spoke of the importance of an early diagnosis and related three cases in his own practice where delay had done great harm, simply because he could not get any consultant to agree to an operation until too late.

This was discussed by Dr. J. W. Chambers of Baltimore.

Dr. Stonestreet related a case of a man 60 years old who broke his femur while sitting on the edge of the bed, just as he was in the act of lifting his feet off the floor.

Dr. Welch did not think that injury was ever the cause of a genuine tumor unless there was a predisposition behind it. He believes in the inheritance of embryonic remnants, and thought the traumatism was only the exciting cause.

Dr. Robert L. Randolph then made a *Report of Fifty Consecutive Operations for Cataract*. This was discussed by Drs. Herbert Harlan, of Baltimore, and Muncaster and E. O. Belty, of Washington.

American Electro-Therapeutic Association.

First Annual Meeting of the Electro-Therapeutic Association, held in Philadelphia, September 24, 25 and 26, 1891.

(Continued from page 934.)

Dr. Robert Newman, New York, read a paper on

ELECTRICITY IN CARCINOMA.

The object of this paper is to give the different ways in which electricity has been used in the treatment of cancer, and to show that cures have been reported which cannot be doubted. Four different methods have been used:

1, Galvanism; 2, electrolysis; 3, galvano-cautery; 4, a combination method, consisting of two of the former.

1. *Galvanism*.—This has been applied externally with pads or sponge electrodes, and (the interrupted current) with needles.

The external application by the galvanic (constant) current with two sponge electrodes to the skin, on or near the tumor, has not met with success, and it seems has only stimulated the cancer cells to greater proliferation, and has thereby hastened the end. Author is not acquainted with a successful case by external application of galvanism.

The second method, by the interrupted galvanic current with needles, deserves more earnest consideration. It was inaugurated recently by Dr. J. Inglis Parsons, of London, who calls it "The arrest of growth in cancer by the interrupted voltaic current."

2. *Treatment by Electrolysis*.—In the treatment of cancer by electricity, electrolysis has been mostly used, and is best known. It differs widely from the former method of galvanism, which, by a strong mechanical action, is expected to destroy the cancer, just as the alternating strong current kills in electrocution. Electrolysis, on the other hand, either destroys, causing decomposition by its chemical action, or causes absorption, according to the strength of the current employed. The art of applying electrolysis successfully consists in using the correct strength of electric current, applying the respective poles in the right place, selecting the size, shape and material of the electrode, and regulating the duration and intervals of sésances.

There are two methods in vogue, one causing destruction, the other absorption. A mild current can effect absorption only; a strength from 5 to 30 milliamperes may be used, and even more, according to work done. A strong current, from 25 and upwards to even 200 milliamperes (and some operators have used even more) will destroy tissues to such a degree that the tumor may slough off as a dead mass. A good rule is to apply the current not stronger than necessary to accomplish the object.

INTERPOLAR ACTION.

It is undecided whether there is an interpolar electrolysis. It is only certain that the decomposition by electrolysis is most at and around the terminus of the poles. From experiments made by the author, it seems that the electrolytic action extends around the needle in a radius of $1\frac{1}{4}$ to $1\frac{1}{2}$ inches.

The conclusions are, that electrolysis can destroy cancer cells, and that electrolysis causes specific decomposition at the pole and within a radius of 1 to $1\frac{1}{2}$ inches. Therefore, if needles are inserted in a tumor at a distance of $2\frac{1}{2}$ inches, it may be expected that the electrolysis acts in such a manner that no interstices are left between the needles which will retain the life of cancer cells. According to such conclusions, author has operated principally by two methods. If an absorption by electrolysis was intended, the whole tumor was electrolyzed in sections with needles connected with the negative pole, one, two or more needles in the tumor at a time, while the positive pole was applied as a large pad outside on the cuticle or near the tumor.

The second method is by having needles from both poles, the positive pole (a single needle) in the centre of the tumor; the negative needle or

needles at the circumference or even outside, but near the margin of the tumor in a manner, and at the distance mentioned before. This was applied for the destruction of the diseased mass, to be sloughed off. In the first method by absorption weak currents were used and no anæsthetic, as no pain was caused.

Reports of cures of cancer by electrolysis have been made by Nefel, Beard and Rockwell, Mussey, Gunning, Ernest Wende and the author. Some photographs of Dr. Wende's cases were exhibited.

Author commenced, in 1874, the electrolysis treatment in cancer, and has had considerable experience with these maladies. The results varied; some were failures, some patient's life was prolonged, and there were also cures, some patients remaining well without any sign of recurrence of the growth for many years. It would take too much time to relate these cases here in detail; only one case has been published, the specimen being presented to the New York Pathological Society and examined by the Society's committee on microscopy, and other experts. Here are some microscopical slides and drawings belonging to this case, for the inspection of the members of our Association, which has and still can prove that the case was carcinoma beyond any doubt.

The case mentioned under the former chapter of the Parson's method, was treated by the author entirely by electrolysis, and shows what benefit was given thereby even in an entirely hopeless case, and it is not the end, as the patient still lives. A case of epithelioma of the face treated by electrolysis in which no recurrence of the disease occurred in seven years, ought to be counted as cured.

3. *Treatment of Cancer by Galvano-Cautery*, has been done by many; but it seems that Dr. J. Byrne of Brooklyn has had the greatest experience and success. Out of 367 cases thus treated, there was no return of the disease in two to eight years in 153 cases.

4. *Treatment by a Combination*—This consists of an application of two of the former methods, mostly combining the application of the electrolytic and the galvano-caustic effect of the battery in the same case.

Cancer grafting has been recently practiced, and from such experience and reports it may be concluded, that cancer in such cases had been exterminated, and therefore that cancer can be cured.

In what Manner is Electricity Expected to Cure Cancer.

The entire removal of the cancer cells ought to cure cancer, no matter what method is used. Now the question arises, how is this effected by the use of electricity. There are several theories and methods.

1. Strong currents of galvanism are expected to destroy the cancer cells by a mechanical action.

2. A removal of cancerous tumors by extirpation (amputation) is effected by the galvano-cautery.

3. Electrolysis by a mild current acts as an absorption by chemical decomposition.

4. Electrolysis with strong currents acts as a destruction. The strong current will destroy the malignant tumor, leaving a dead mass, which will suppurate and finally slough off, leaving a healthy surface, healing by granulations.

Whatever method is used, it must be done thoroughly and systematically, removing all cancerous cells. Success can only be expected in the earlier stages of the disease, when the malady is local and the malignant mass is concentrated in one small tumor. If the cancer cells are dispersed in different parts of the body, scattered, and the disease has advanced, success cannot be expected.

The Advantage of Electricity Against Other Methods.

1. The facility with which electricity is applied, some methods can be done without an assistant and without an anæsthetic.

2. The operations are free from danger.

3. It causes no shock after the operation.

4. It is easier to get at the whole of the disease in an early stage, than by any other means.

5. It can be used in anatomical dangerous places, beyond the reach of the knife, and the horror of the knife is avoided.

6. It delays the growth, prolongs life and benefits the patient, even if it does not always cure.

7. The patient is not necessarily confined to his bed or house.

8. The operation does not cause pyæmia or septicæmia.

9. There is no danger of hæmorrhage, but it controls hæmorrhage.

10. There is more chance of a cure and better healing after the operation.

11. It always allays pain.

In the foregoing article the details of cases have been omitted; it would have made it too long; it has not been written for the general practitioner.

The object was to report the different electric methods which have been used in the treatment of cancer, before the meeting of experts in electricity, for discussion and improvement.

Dr. Hutchinson:—I am very glad to have listened to Dr. Newman's paper. I have personally known a great many of his cases.

So far as cancer is concerned we have been in touch many years. I have operated on sixteen cases myself. Two are still living. One a case of epithelioma of the lower lip removed fourteen years ago. He has not had any return of it and

is in good health at present. The other is a woman from whom I removed a breast and her two labia majora, and after twelve years she is in good health. These cases are both a matter of record.

I think cancer is curable by galvanism, and I think in some cases where it has become constitutional they are so to some extent; that is, where cancer has become infiltrated through the system by local tumors, the removal of those tumors and taking away of the irritation has resulted in final cure, or at least in great relief.

Dr. Bigelow: In one of the late numbers of a French journal there are some notes upon epithelioma and keloids which have been treated by the same method as that of Dr. Newman. The writer also has under observation now three other cases, and if after the lapse of two or three years he will know whether the lymphatic system has absorbed any of the virus, then we will be able to say whether or not the cases have been cured. We have two cases now which will be published shortly.

Dr. Hayd: Since my name is alluded to in Dr. Newman's paper I gladly arise to say what I know in reference to these cases.

There is no doubt whatever that in the case named the person was cured. He is the official stenographer of the court, and had had it several years. He had been treated by several methods. The growth was twice removed by the knife and twice he went to so-called cancer specialists and had some caustic applied; in all probability a preparation of arsenic. He was also treated with cod-liver oil applied locally, as it was thought by some to be a case of lupus. I saw the man last week, who came to me desiring to renew an insurance policy, and I am pleased to be able to tell you there were no nodules or tubercles and no ulceration. The sore, which had been unsightly two years ago, has now healed, and in place of an ugly cicatrix he has a clear face and scarcely any scar to be seen.

Dr. Wend has done a great deal of work in this direction, and his reports can be accepted as from a well-qualified man fully competent to express an opinion upon this subject. He is professor of the diseases of the skin in the Buffalo Medical College, and whatever he writes is written with honesty of word and intention, and these cases I can verify, as I have seen them. None of you, if you saw this case now, would have any idea that he had had any malignant ulceration; it is not noticeable.

Dr. Walling: I have had a little experience in these cancer growths. A case in which Dr. Massey kindly assisted me in Parson's method, and which was referred to by Professor Goodman, the patient had lost his hand from the growth some years ago, and now the growth had appeared in the left axilla. The whole left side

was involved. It was of a dark purplish color and he was suffering a very great deal of pain, and I advised him to have the arm taken off at the shoulder, but he preferred to have the electrical treatment. I used Parson's method and 600 milliamperes with repeated alternations of current. On the back side of the arm was an ulcer the size of a walnut, which had broken out from degeneration. I thrust eight needles—four platinum and four steel—into the growth. Inadvertently the current was run up to one ampère and the needles dropped out. The consequence was we had a deep slough. The tissue under the positive needles was almost like cartilage and I was afraid I would not be able to heal it up, and that it would degenerate below and I would have a bad case; however, I took the negative carbon and acted upon the apparently cartilaginous tissue and cleaned it all out from time to time, and it healed up entirely notwithstanding the continued irritation of the parts, making application of the positive current until it was all cleaned up, and although the result of this operation did not succeed as we had hoped, it so checked the growth that I repeated the operation up to fifty milliamperes with the result of checking the growth for a long time, but as it was deeply seated in the axilla, we could not reach it on account of the larger vessels. The ulcer was treated with carbon electrodes passing deeply in and keeping it clean, and syringing it with an antiseptic, as well as keeping it covered with boracic acid and cotton; finally it ulcerated through a large artery and the man died.

Another case which came under my care in the Medico Chirurgical Hospital was a case of epithelioma of the face, and this was cleaned out by two operations. It was acted upon by the negative needles, using fifteen milliamperes without an anæsthetic, and by acting on the surface with the negative carbon with rather deep action. The surface healed over in about three weeks' time. I have not seen the case for six months, but I believe those things can be cured if taken in time.

Dr. Morton: I do not like to keep my seat without thanking the author for his excellent handling of the subject. I have had no experience whatever in treating cancer with electricity, but I recall that his paper is a resumé of the former operations, and the methods he outlined we leave out of view, which I imagine he views as an amputation procedure. It opens up such a large volume of fact and speculation that we cannot go into it; but it involves this treatment of cancer and cancer growth by the direct action of the needle, and involves the electrical treatment. I hardly see how you can say that the galvanocaustic treatment is not purely electrical as well as a chemical treatment. The very fact that you use a sufficient current to produce an electrolytic

product at the point of the needle is the best evidence in the world why you are using sufficient current to produce those profounder effects which you would like to have gotten with the galvanocaustic treatment. When you use the galvanocaustic and galvano cautery treatment you cannot separate them.

The peculiar part of the whole thing is, as I understand from the reader's paper, that electric energy has a peculiar selective power to act upon the cancer cells and not upon the healthy cells, otherwise I cannot see how a distinction can be drawn between the galvanic treatment and the knife. If the galvanic treatment has this selective capacity, that is the point that should be made clear. I think I should like to have heard a little more discussion about the varieties of cancer. It seems to me that a great many of the results are in epithelioma, and I think that dermatologists claim good results from other treatments than electricity. Dr. Fox showed me good results from other treatments.

Dr. Massey: I must join Dr. Morton in commending the paper as not only careful, but very moderate in its statements, and we should be careful of promise in such desperate diseases. We want to get at the facts in an exact manner when we have to deal with one of the worst scourges of the human race, and one, so far, which has been apparently entirely resistant to medical treatment.

It was only yesterday, at a meeting of the American Gynecological Society, that a discussion occurred on hysterectomy for carcinoma of the uterus, and I was struck with the failure of surgery also to accomplish striking results. Recurrences seem to be alluded to often in speaking of cases, unless they were distinctly minute in their seat at the time of operation, that it must be regarded as almost an entire failure. The question of the cautery does not come into consideration here, it being merely a thermic knife, and thermic destruction of tissue. To my mind the other question, of a possible value of electricity in killing the cancer germs themselves, is of far greater importance. Allusion has been made to the question of selective affinity to cancer cells. I scarcely think that is a good way to put it, to describe what I regard as a fact.

The cancer cell is a highly liquid infiltration of more solid tissue—I now allude to epithelioma—and in addition to that fact, presents another reason for lessened resistance in that lowly organized tissue. I think it can be well demonstrated that more current will traverse a cancer than a non-cancerous tissue. Then again, cancerous tissue is possessed of low vitality, and probably therein lies the greatest power we have to electrically kill it. Surrounded as it is by more highly organized tissue, it cannot resist the onset of a strong current or strong chemical action, and

hence it may be amenable. If amenable, how much better is such a practice for good, for the cancerous infiltration is followed back into its habitat, or more correctly stated, back through the lymphatic tracks that lead into the more healthy tissue.

My own experience in this subject has been mainly with epithelioma of the cervix. I have used methods different from any mentioned. I am not sure whether they are entirely novel. It is simply a direct application of a strong current on a limited surface, of the carbon positive pole directly to the diseased tissue. In that way, the parts being free from excessive sensation, I accomplish the ready destruction of cancerous tissue. You can at once accomplish the immediate cessation of bleeding which annoys and weakens the patient. I have in one application, with less than 100 milliamperes, arrested a hæmorrhage which had lasted a year, and the hæmorrhages have never recurred. It arrests hæmorrhage quickly, and the cancerous tissue will afterwards come away, under the influence of antiseptic douches, in white crumbs, and leave a clear, hard excavation where the cancer had been. In one old case in which there was not sufficient treatment, there was no question about the prevalence of cancer in other parts of the body. Excavation finally resulted where the cancer had been which would admit two or three fingers, which became lined with a healthy material. This was curetted with the idea of seeing if any cancer cells were left, and Dr. Crozier Griffith, who is one of our best microscopists, decided there was not. This person finally died of cancer of the liver. These cases have been unfortunate in being treated at a period of the disease when they could not be benefited, but I am sure that if the cases are taken early, cure can be accomplished.

I assisted Dr. Walling, as he relates, in using the Inglis-Parsons method in the case related by him, and I think we used it quite strictly, but the case, as he has said, was most unfavorable, as it had reached the bones before we treated it, but it suffices to show the value of the Parsons method. The accidental use of 1,000 milliamperes was on account of a too close apposition of the needles.

Dr. Morton: Before taking my seat, I would like to ask the author of the paper as to whether the effect he obtained was due to actual electrolytic decomposition by the chemical products of the electrical current; in other words, how much is due to electrolysis and how much to the caustic effect.

Dr. Blackwood: The remark just made, that the electrical current has a greater effect on cancerous tissue than upon the normal, is, I think, correct. In a case which I saw some time ago, where a surgeon attempted to persuade the patient to go under an operation, but which she at

that time refused, and upon whom I was permitted to use the electric current for several applications, the uterus was bound down and she was very uncomfortable, and it was difficult to get the needles in properly. I noticed that the action was very destructive on the cancerous tissue and not upon the other tissue. But finally the surgeon obtained more influence upon her than I could bring to bear, operated upon her and buried her.

Dr. Waite: I saw one case of Dr. Wende. He used after his ordinary treatment the faradic current, which he thought prevented the case from going back, and he usually makes the application fifteen minutes after the treatment with the needle.

Dr. Newman: In summing up, the only thing which I have to do is to answer the question of Dr. Morton.

It is true I never thought that the galvanic cautery was strictly a chemical action, but at the same time I think it applies to electricity, so that I gave it a distinct division in the treatment. While it is in the line of surgical action, I think the electricity has something to do with it, but how much of either it is impossible for me to say.

The other question, to say how much in this treatment is due to electricity *per se*, or electrolysis, I do not feel competent to say—I do not feel competent to speak, as I am biased, as I am enthusiastic about it. I am known to attribute the effect to chemical decomposition, and I believe that the principal action by which we do this, or get these effects, in the cure of cancer, is by electrolysis and its chemical decomposition. This chemical decomposition may be of a twofold character; the weaker is an absorbent, and the stronger a destructive. It is certain that the electric action has a good effect. I have on purpose not given any opinion of my own.

I have given the method of Dr. Parsons, which I believe in some cases to be impossible to use. Imagine the application of 600 milliampères on the left side near the par-vagus, what would become of the patient? I do not feel competent to express an opinion as to this method, either praising or condemning it, without more experience.

Electricity has certainly an action. Some think it is a plaything, but it has killed many patients.

To go further and deeper into the subject as suggested by Dr. Morton, I feel incompetent to do. The material on hand was so overwhelming when I commenced to write my paper, that I had considerable difficulty to bring my paper within compass, and it is much larger now than I should have made it, and I tender to you all my sincere thanks for your careful consideration.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopaedic Surgery.

Stated Meeting, November 20th, 1891.

SAMUEL KETCH, M.D., CHAIRMAN.

A CONVENIENT DRESSING FOR CASES OF TORTICOLLIS AFTER OPERATION.

Dr. R. H. Sayre presented a boy upon whom he had operated twelve days before, for the relief of torticollis. The case illustrated the form of dressing which he had found very useful after such operations. It consists of a plaster of Paris jacket and a jury-mast, the upper part of which has a fan-shaped expansion fitting the occiput. After a thorough subcutaneous sub-division of the sternal and clavicular attachments of the muscle, the boy was allowed to come out of the ether, and then a tightly fitting foot-ball cap was pulled down over the ears and covered with a plaster bandage, which also included the expanded portion of the jury-mast. In applying this dressing, care was taken to place the head in the normal position. The mechanical appliances usually employed for the after-treatment of these cases is difficult and tedious to make, and must be made for each patient, and even then are hard to keep in position.

Dr. A. M. Phelps considered this the most efficient dressing of its kind which he had seen.

Dr. N. M. Shaffer did not share the opinion that the mechanical appliances ordinarily employed were complex, and difficult of application; on the contrary, he thought they possessed a distinct advantage over this fixed plaster dressing, as they allowed of frequent but slight changes of position, and a gradual restoration to the normal position. The case just presented, did not show a complete correction of the deformity. In two recent cases of club-foot in which he had endeavored to fully correct the deformity at once, too long a tendon was the result.

Dr. L. A. Sayre said that he had employed this dressing for the last ten years to the exclusion of all others, and had found it more efficient than any he had previously tried. The principle of practice laid down by the previous speaker, he considered erroneous; immediate and full correction of the deformity was much better than tormenting the patient at short intervals by frequent stretchings of partly adherent tendons. If proper judgment were exercised, the tendon should not be too long.

Dr. Phelps said he wished to heartily endorse the principle laid down by Dr. Sayre. The English method of gradually reducing the deformity by stretching, was, in his opinion, a fruitful source of non-union of tendons, and of their adhering to their sheaths. He had never had a single case of non-union of tendons, and he always divided them thoroughly and super-corrected the deformity at once.

Dr. R. H. Sayre, in closing the discussion, said that in certain cases of wry-neck where stretching was preferable to tenotomy, the Archimedeal screw and other mechanical appliances usually employed, were very effective, but if the tissue be contractured, and hence required tenotomy, he thought the dressings he had just shown would be found to give more perfect fixation of the head. Immediately after the tenotomy, a certain amount of material is poured out between the ends of the divided tendon, and a large gap can be filled up as easily as a small one. As the amount of this exudation neither increases or diminishes after the first effusion, it follows that if the position were not fully corrected at the time of the operation, subsequent stretching can only produce elongation of the tendon at the expense of its diameter.

Dr. Halsted Myers presented a case of

LUMBAR POTT'S DISEASE,

with a very large abscess occupying the right side of the abdomen from the ribs to the pelvic brim, extending nearly to the median line in front.

The boy's general health was excellent. He was fat and ruddy. His bowels were regular. There was no albumen or casts in his urine. There was no enlargement of the liver. His temperature varied between 98° and 99° F.

The patient was presented to illustrate a not small class of cases, and to prove that very large cold abscesses can and do exist without causing any disturbance of the general health.

Dr. Thomas H. Manley thought the lesson to be learned from such a case, was that extreme conservatism should be exercised in the treatment of abscesses where they do not give rise to pronounced constitutional symptoms.

The Chairman was of the opinion that one of the most important lessons which the orthopaedic surgeons had impressed upon the general surgeons, was that many cases of abscess disappear under proper mechanical and constitutional treatment. He would even go further, and say that many abscesses were prevented by such treatment, and that as these methods more nearly approached perfection, abscesses would be less frequent complications of Pott's disease. While admitting that at times it was very difficult to decide as to the advisability of operative interference, he was personally of the opinion that in cases of joint or spinal disease, there was less risk from the non-operative treatment, for the reason that pus in a closed cavity is much less dangerous than after the cavity has been exposed to the air.

Dr. Phelps said that in the case just presented, the abscess was probably really a cavity filled with tubercular material, and free from the germs of suppuration; but while such "cold abscesses"

might remain for a long time without doing any harm, they were liable sooner or later to become infected with pyogenic germs, and when this occurred, "burrowing" would begin, and the patient would exhibit all the usual symptoms of sepsis. As there was no means of telling when such infection would occur, he thought it wiser to operate on all of these cases. He felt perfectly confident that he could operate on all such cases without any danger from sepsis, and he had never seen any deaths attributable to such operation in his hands.

Dr. Shaffer said that this theory sounded very nicely, but a large hospital experience extending over a period of twenty-eight years, during which time he had tried various methods of treating these abscesses, had taught him to regard them as of no great importance, and he would not consent to opening these abscesses unless there were severe or prolonged constitutional symptoms due to the abscess. If we were wise enough to let these abscesses alone, the patients would usually do better than if they were opened.

Dr. R. H. Sayre said that his experience with these abscesses had been quite different from that of the previous speaker, and he looked upon them as representing a serious phase of the disease. Where the abscess cavity did not admit of safe and thorough evacuation of its contents, so that healing might proceed uninterruptedly, it was better not to operate, unless there was serious constitutional disturbance. Letting all cases of abscess alone was as harmful practice as opening every abscess which presented itself.

A CASE OF TALIPES EQUINO-VARUS SHOWING THE IMPROVED LATERAL TRACTION APPARATUS.

Dr. N. M. Shaffer said that the development of this traction apparatus had been attended by much experimentation and annoyance, and during this period, there had been naturally a number of failures. A large number of cases of pure equinus which would ordinarily be condemned to tenotomy, could undoubtedly be cured in this way, but in the more complex deformity, known as equino-varus, the mechanical conditions were much more intricate. The first two cases which he presented were intended to show the good results which had been obtained without the latest improvement, and the third one, to show the improved apparatus applied to the patient, as well as to exhibit the result of three month's treatment. In the older instrument, there were three movements, viz.: 1. One which put the foot in any position as regards the equinus; 2, one which threw the foot outwards as far as desired, and locked it there; and 3, one which drew the foot around into a valgus position. It had been found in cases which had been treated

by this apparatus, and were apparently cured, that there was inward rotation of the whole foot on a vertical axis, and the object of this latest improvement was to correct this defect. It consists in extending the apparatus up to a pelvic band, and introducing a fourth movement, by which the whole foot is turned on the vertical axis.

The girl whom he exhibited with this apparatus, had been admitted to the Orthopædic Hospital on August 27th, with such a severe type of double equino-varus, that he thought many would have advised operation. The four movements which he had described had been made "up to the point of toleration," and repeated many times a day. They were executed in the following order: 1. Bringing the foot up while the heel is held down; 2, throwing the foot outward and keeping it there; 3, turning the whole foot on a vertical axis; and 4, throwing the foot into a valgus position. While the third movement is being made, it is noticeable that the patella does not move. The results he had obtained with this new apparatus were remarkably quick and satisfactory.

A STUDY OF ONE OF THE ETIOLOGICAL FACTORS OF LATERAL CURVATURE OF THE SPINE.

Dr. Charles L. Scudder, of Boston, presented the results of an investigation into the seating of 3,500 school girls, with especial reference to the effect of poor seating upon spinal deformity.

Lateral curvature of the spine is in all probability due to several factors: 1, the superincumbent weight of the body falling upon a spine weakened either in bone, muscle, or ligament; and 2, held persistently out of the median antero-posterior plane of the body.

Dr. Scudder made a careful examination of the seating in schools, and found that faulty positions, one of the elements of the third etiological factor, are certainly induced because of the lack of adaption of seat to pupil and pupil to seat. How much of a factor in causing lateral curvature poor seating is, it is impossible to say, but that it plays an important part there can no longer be any doubt.

The author suggested that the present seating arrangements of schools be used to better purpose than hitherto, by arranging scholars more carefully in the room, and having careful supervision exercised by those in charge.

He then described the development of the adoption in the Boston Public Schools of the Swedish Gymnastic system, and regarded it as of highest importance as a measure likely to be somewhat preventive of spinal curvature induced by poor attitudes in sitting. This is to be brought about by no specialized gymnastics, but by general, central movements which shall tend to develop the whole child along the lines of his natural muscular development.

Dr. L. A. Sayre said that if proper attention were paid to the physical training of girls, there would be few cases of lateral curvature.

Dr. V. P. Gibney said that the paper reminded him of some observations he had made at one time in our public schools. In passing through the schools he had been struck with the frequent changes of position of the pupils, and he had concluded that faulty attitudes were not so potent a factor in this condition as he had previously imagined. He was, however, willing to admit that it was quite possible that weak children having once assumed a comfortable attitude, would be likely to maintain it long enough to be injured thereby.

Dr. Ramon Guiteras agreed with the author as to the great importance of the Swedish gymnastics in the training the bodies of young children. As to the matter of desks, he was happy to say that school desks and chairs had recently been invented by E. E. Hicks, a student of the University, which could readily be adapted to any height.

Dr. H. L. Taylor said that the author had shown indisputably the necessity for competent medical supervision of our public schools. As lateral curvature occurs rather more frequently among the children of the well-to do class, who as a rule, attend private schools where the seating of the children usually receives more careful consideration than in the public schools, and as this deformity also sometimes develops among children who have been entirely educated at home, he was not willing to admit that faulty school attitudes were very potent in producing the deformity in question. They undoubtedly do children harm, with the production of lateral curvature. The instinct of young children is to keep in motion, and one of the great faults in our system of education is the absence of frequent short recesses. A recess of five minutes between each recitation, especially if utilized for gymnastic exercises, would prove very beneficial, and he hoped the paper would receive that wide and thoughtful attention which would lead to the introduction of rational physical culture into our school life.

The Chairman said that his own impression was that no habit in itself, no matter how long continued, could produce an idiopathic rotary lateral curvature of the spine. Some years ago, he had written upon the etiology of this condition, especially in young children, and had called attention then to the fact that the curvature was present before the children assumed these faulty positions, or in other words, that the position was the result of the curvature, and not the cause. He was willing to admit, however, that a *curve* of the spine could be produced by a long continued bad position.

Dr. Scudder, in closing the discussion, said

that he recognized that among the many factors which entered into the causation of lateral curvature, three important ones were, the superincumbent weight of the body upon the spine, 1, weakened by a diseased condition of the bone, *e.g.*, rickets; 2, weakness of the muscles (not yet demonstrated); and 3, weakness of the ligaments. Although it was not yet known whether one or all are present in any given case, it was known that the superincumbent weight of the body falling upon a spine which is kept in the median plane of the body, causes only an antero-posterior curve. This was known both by demonstrations on the cadaver, and by observations on the living subject. But when the spine deviates from this median plane, a certain amount of lateral curvature results. His paper embodied a study of the effect of faulty positions on the body, and did not assert that faulty positions in themselves caused lateral curvature.

THE ANATOMY AND MECHANISM OF THE FOOT
WITH SPECIAL REFERENCE TO TALIPES;
AND THE EXHIBITION OF A SHOE
FOR CLUB-FOOT.

A paper with this title was read by Dr. James E. Kelly. He indicated the relation of the progression of terrestrial animals to cyclical motion, likening that of bipeds to a unicycle in rapid motion, and a lateral bicycle, such as the "Otto," in slow motion, while a quadruped resembled an ordinary bicycle in rapid, and a quadricycle in slow motion. He indicated the relation of the pelvis to the "hub" or nave of a wheel, the thighs and legs to the spokes, and the feet to the rim or tire. Great economy was claimed in weight, space, labor, and nutrition by the substitution for the entire wheel, of two spokes, and the corresponding tire segments of feet which alternately assumed the functions of the numerous portions, each oscillating as a complex pendulum, and describing the brachistochrone or curve of the most rapid descent. He exhibited a model which reproduced the movements very accurately.

Dr. Kelly controverted the accepted description of the foot as consisting of antero-posterior and transverse arches, and demonstrated the fact that the two feet placed together constitute a dome or cupola, the entire margins of which rested on the ground, and consequently, one foot might be more properly termed a semi-dome. He proposed an original explanation of the advantages we derive from the outer toes being the shorter, in the fact that when the semi-dome revolved on its margin from the posterior to the inner anterior portion corresponding to the great toe, while the body moved forward, the consequence was that the ankle was bent outwards and placed in the most favorable position for clearing the inner side of the opposite foot when swinging forward to assume its anterior position.

He dwelt on the nomenclature of talipes, and suggested the term "talipes ankylosis," for that form described by Dr. Schaffer as "non-deforming talipes." He entered into the mechanism of talipes more especially with regard to the type than the particular form, and reduced the factors of deformity to extension, luxation, and torsion, and indicated their participation and isolation in various deformities. He also spoke of the influences which produced the deformities, as modelling pressure and adaptive growth, and indicated that mechanical treatment was limited by the extent to which the same factor could be utilized in rectification. The question of operation was to be decided by the same standard. He exhibited some diagrams which demonstrated the theoretical advantages of the removal of the wedge-shaped pieces of bone, with the careful avoidance of the articular surfaces, from the calcaneum, the internal cuneiform, and the tibia in talipes valgus, and the comparatively great rectification which could be obtained by the excision of very limited wedges. The author dwelt upon the ease and safety with which all portions of the tarsus could be approached through incisions along the margins of the foot, owing to the stratification of the structures forming the sole, and advocated the section of the plantar ligaments by an oblique incision parallel to the tendon of the *deroneus longus* from the outer side, and the freeing of the cuboid bone by a curved incision from the inner margin of the foot.

Dr. Kelly also exhibited an apparatus which he had invented in 1881, and first demonstrated before the Massachusetts Medical Society in 1884 or 1885, in a discussion on a paper read by Dr. Edward H. Bradford on "New and Original Methods of Treatment of Club-Foot." The appliance consists of a boot with a metal sole-plate, a pair of strong drawers with a "box knee-cap," and a number of slight elastic bands. The plate resembled a segment of a saucer from which the steadying rim had been removed. The boot was placed on the flat central portion and had a number of holes along the elevated margin from which the elastic bands passed to the lower band of the box knee-cap. The apparatus utilized the weight of the patient's body as the rectifying force, as at each step a part of the curved portion of the plate coming in contact with the ground, rolled it over until it reached the only part that afforded stability, namely, that upon which the foot rested, and consequently the member was forced into the most advantageous position. The elastic bands were added for the two-fold object of maintaining, during repose, the benefits derived from locomotion, and of exercising lateral torsion on the foot by an easy arrangement of the bands with regard to the plate and the knee-cap. He expressed the belief that the shoe in its present shape would be useful in

the less aggravated forms of talipes equinus and varus, and as an adjunct in the treatment of the more severe examples.

Southern Surgical and Gynecological Association.

Fourth Annual Meeting, held in Richmond, Va., November 10, 11 and 12, 1891.

(Concluded from page 936.)

THIRD DAY—AFTERNOON SESSION.

Dr. Paul B. Barringer, of Richmond, Va., read a paper on *Venomous Serpents of the United States and the Treatment of Wounds Inflicted by them*.

Dr. Christopher Tompkins, of Richmond, Va., followed with a paper entitled

A CASE OF INDUCED ABORTION FOR RELIEF OF NAUSEA AND VOMITING, WITH REMARKS.

On August 1, 1885, he was called to see Mrs. J., aged 24, and, as nearly as could be ascertained, three and a half months pregnant with her first child. Patient was born in the mountainous part of Virginia; she had an active outdoor life and grew up to be a woman of good height and of round full figure. January 14, 1884, she was married.

While in the city of New Orleans, in stepping from the platform of a car, she sprained her ankle. This, although treated immediately by a physician of that place and subsequently in this city, caused her great suffering. Finally, refusing to yield to the usual treatment, the part was put in a plaster cast; she went about on crutches, and after many months recovered. In the meantime she became pregnant and from the first was attacked with nausea and vomiting. Mild in the beginning, it gradually increased in gravity, till she sent for him on the 1st of August, 1885.

Her husband stated that she had had fever for two weeks. He found her in bed and learned that she had been there for days; her figure not robust, and her face thin and attenuated. What little she had eaten in the past ten days or two weeks had been apparently rejected, her temperature one degree above normal; tongue foul; sordes on the teeth, and the breath of a sour and bilious odor. The pulse was fairly good, considering her condition. Even the mention of food was distressing to her, and the sound of the dinner bell, though far off from her, caused such distress that its ringing was discontinued by the family. The bowels had throughout her pregnancy been constipated, only moving once in two or three days. Although continuously retching, very little or no blood had been seen in the material vomited, except on two occasions, and then not a great deal, and such as there was

was of a florid, scarlet color. No medicine had been given and no treatment taken, except the occasional use of lime water, which she said "did no good."

The patient did not improve up to August the 7th, when Dr. Tomkins, thinking the case one of the greatest gravity, and that the question of abortion could no longer be deferred, invited Drs. J. B. McCaw and Aaron Jeffery to meet him in the afternoon in consultation. All agreed that abortion must be produced, in order to give the patient a last chance for her life, which was done.

REMARKS.—The case is reported principally because it was an unsuccessful one, and because he wished to disabuse the minds of those who are not experienced in such operations of the notion, commonly believed, and often expressed, that the induction of abortion for the nausea and vomiting of pregnancy is in skillful hands an undertaking devoid of danger and necessarily attended by success. In this case, he is of the opinion that death was the result of the protracted ability and enfeebled constitution, due to her long confinement and suffering: First, from the injury to her ankle, from which she had not recovered, when she became pregnant and was attacked by nausea and vomiting, this last continuing till her death. Under such circumstances the outlook was indeed very unfavorable, for to the shock of operation and depression incident to the use of chloroform, there was added fever and protracted prostration, both from injury to the ankle and from want of nutrition, the result of the long existing nausea and vomiting. He had before and since operated on women for the nausea and vomiting of pregnancy and with success, whose apparent condition was much worse than that described in the above case, but without the history of a previous injury or disease.

The prognosis, always unfavorable, ought, when the case is so complicated, to be of the most guarded kind. The practitioner should not, however, hold his hands on this account, for the operation affords the poor sufferer the only opportunity of relief. The author uses metal dilators instead of tents, and completes the operation at one sitting. He is likewise convinced that the least possible chloroform used, the better the result.

Dr. W. E. B. Davis, of Birmingham, Ala., presented a paper entitled

TREATMENT OF GALL STONES, WITH CASES.

He said: "The treatment during the attacks consists in hypodermics of morphine and atropine, with the use of ether and chloroform until the other remedies have had time to take effect. It is usually soothing to place the patient in a hot bath: and large draughts of hot water will relieve the distressing nausea.

After gall-stones have formed, experience does not warrant us in placing confidence in medical treatment for their cure. The sweet oil draughts, as has been abundantly shown, only become saponified, and give rise to stone like masses. Turpentine, chloroform and wild yam are not curative.

Perhaps something may yet be found that, when injected into the bladder, will dissolve the stones. This is especially desirable for stones located in the ducts. It would seem that medical treatment would prevent their formation; but, so far, there is no very good evidence to show that any medicine has this effect.

A stone in the gall bladder produces such a condition as to favor the formation of other stones; and after an operation for the removal of the stone and the relief of the local condition, we have no return of the disease except in a very small per cent. of cases. This is so in those cases in which stones had been forming rapidly before the operation, and would go far to show the importance of the local causes of the disease. Then, in addition to general tonics, iron, phosphate of soda, mineral waters, etc., our dependence must be placed on operative procedures.

In some cases it may be difficult or even impossible to make a diagnosis of gall stones, but it has been said very correctly that the mistake is much oftener made in calling gall-stones something else than of calling something else gall-stones. Paroxysms of epigastric pain, with tenderness over the lower hepatic region, accompanied with bile in the urine, and followed by clay colored stools, and sometimes the passage of stones, are the symptoms on which dependence must be placed. The shoulder pain is rarely present, and jaundice is most frequently absent. It is only when there is obstruction in the hepatic or common duct that this symptom is to be expected; and often the obstruction is so evanescent as not to give rise to sufficient obstruction to produce jaundice.

When there are frequent attacks of biliary colic, it is best to operate and give the patient the benefit of the exploration, and avoid the dangers of a peritonitis. It is not conservatism to delay operation, where there are obstructive symptoms, until the liver has become involved and the patient's blood poisoned. He had seen a number of these neglected cases in which an operation could offer no chance whatever. He reported a case of death from peritonitis following repeated attacks of biliary colic, where there was sufficient warning to save the patient, but her physician would not advise an operation. In some cases, however, there are no symptoms to indicate the presence of a stone, until peritonitis has resulted from ulceration thus induced. During the past month he had operated on such a case at Ashville, Ala., for Dr. D. E. Cason. The patient

was a woman 74 years of age, and had never experienced any symptoms of gall-stones.

He recommends cholecystotomy, and opens the bladder and sutures it to the parietes at one operation. He reported a case in which he removed 51 gall-stones from the bladder, one of them being impacted in the cystic duct, and the patient made a perfect recovery.

Cholecystectomy, the removal of the gall bladder, should never be an operation of selection, and only resorted to when cholecystotomy is not possible. Do not stitch the bladder to the parietes and wait for adhesions before opening the viscus, as it is necessary for it to be opened and emptied before the abdominal wound is closed, in order to recognize conditions which will require manipulations within the abdomen as well as within the bladder. Stones impacted in the ducts must be dislodged and pushed into the bladder or duodenum. It may be necessary to break them up with a needle before this is possible. In some cases the duct should be incised and sutured. Where the obstruction in the common duct can not be relieved, cholecysto-enterostomy should be resorted to.

The following officers were elected:

President—Dr. J. McFadden Gaston, Atlanta, Ga.

First Vice-President—Dr. Cornelius Kollock, Cheraw, S. C.

Second Vice-President—Dr. Geo. Ben Johnston, Richmond, Va.

Secretary—Dr. W. E. B. Davis, Birmingham, Ala.

Place of next meeting, Louisville, Kentucky, second Tuesday in November, 1892.

Chairman of Committee of Arrangements—Dr. L. S. McMurtry, Louisville, Ky.

MICROÖRGANISMS IN THE NORMAL HUMAN URETHRA (*Centralblatt für Chirurgie*, No. 44).—Messrs. E. Petit and M. Wasserman communicate the results they have obtained by exact microscopical and bacteriological examination of the human urethra. The observations were made upon four of their colleagues who had never suffered from any form of urethral affection. The observers have discovered five varieties of micrococcus, six of bacillus, two of sarcina, and two of torula cerevisiæ, of which they describe the microscopical and bacteriological peculiarities. Both authors comprehend their principal results in the following propositions:

1. The normal urethra always contains different varieties of microörganisms.
2. The same varieties are never found in different urethræ.
3. In one and the same individual a difference is found in the varieties taken from the anterior and posterior portions of the urethra.
4. None of the microörganisms discovered are under ordinary circumstances pathogenic.
5. The greater number, however, decompose the urine.
6. The pseudo gonococcus of Lustgarten and Manna-berg was never found.

It is not possible by the most careful and elaborate antiseptic washing of the urethra to obtain a perfect condition of antiseptis.—*Provincial Medical Journal*.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, DECEMBER 19, 1891.

DIET IN TYPHOID FEVER.

The dictum of "liquid food in typhoid" has resulted in the use of an exclusive milk diet by many physicians. So much so is this the case, that we think we may truthfully say that the orthodox diet in typhoid, as recognized by the profession as a whole, is one exclusively of milk. The advantages resulting from the use of the milk diet have been noticeably great, and it is customary to ascribe these benefits to the bland character of the food. The liquid character of the milk is particularly insisted upon and it is assumed that solid food would be detrimental because of its solidity.

It seems to be opportune to call into question this mechanical explanation of the results obtained with a milk diet. The diminished risk to perforation which it may afford is insufficient; its lack of irritation upon an inflamed bowel, is too indefinite.

In the first place, milk is only apparently a liquid food. Its coagulation into great masses in the stomach, soon after its ingestion, makes it a solid food, without the advantage of subdivision, which other solid foods would have. Moreover, the use of solid foods in ulcerative conditions of the bowels, other than typhoid, is not held to be dangerous. In dysentery milk is not

as well borne as animal broths, and farinaceous foods. Some authorities speak of the disadvantages of milk in the diarrhoea of infancy. Yet, nevertheless, in typhoid fever it has proven the best diet thus far used. If the true reason for its utility be known, the limited milk diet may be extended along proper lines, much to the benefit of the patient. The mechanical reason for its utility is eminently insufficient and unsatisfactory. The reason must therefore be sought in the chemical conditions present.

The stools voided by the typhoid patient may possibly be the result of the action of the microbic cause of the disease in the blood, but it is far more likely that the conditions within the alimentary canal itself, have much to do with their character. The results reported from the use of intestinal antiseptics, by many observers, particularly the sulpho-carbolates as used by WAUGH, indicate strongly that much of the fever, and many of the symptoms produced in typhoid are directly due to the fermentative conditions in the bowel itself. Several years ago RACHFORD¹ made a series of observations on rabbits, designed to elucidate these points. He grew pure cultures of typhoid bacilli, in different culture media, viz.: peptonized milk, peptonized beef, peptonized brain, and bouillon and beef peptonoids. These cultures were introduced into the stomachs of the rabbits.

The rabbits which were fed the beef peptonoid cultures exhibited very pronounced brain symptoms, with elevation of temperature. The brain and beef cultures produced the same effects without elevation of temperature, while the milk cultures produced the mildest type of the affection. RACHFORD's experiments fully justify his conclusions, viz.: "The physiological and poisonous properties of the ptomaines formed by this bacillus [KOCH-EBERTH] will depend in great part on the character of the food material in which it is growing," and "milk is the best diet in typhoid fever, since the ptomaines produced in it do not cause either fever or nervous symptoms."

Now, then, the true reason for the value of milk in typhoid being known, some clue to the means of supplementing it in the right direction is given. Milk is not a complete nutrient for the adult as it is relatively deficient in carbohydrates, and in febrile processes especially are car-

¹ Medical News, Phila., Vol. LV, p. 453.

bohydrates needed. The poisons which RACHFORD's experiments show to be active, are all derived from animal food. Poisons capable of producing nervous symptoms or fever can not be formed from carbohydrates, so that objection to these articles of food on this score can not be urged. They might produce flatulence and increase the tympanites. The mechanical objection to carbohydrates, such as bread, rice, and potatoes is surely exaggerated. The incomplete nutritive value of the diet to which typhoid patients are subjected certainly must have a marked effect in prolonging the period of convalescence, and no doubt also reduces the strength of the patients during the attack to such a degree as to permit a fatal issue which a more complete nutrition would have prevented. In the absence of figures we may be allowed to believe that more deaths would result from this incomplete nutrition, than could possibly happen from perforation under a more generous diet.

Again, the occurrence of severe nervous symptoms may even indicate the complete withholding of milk temporarily, for the purpose of assisting in bridging over a serious episode in the course of the disease.

WHAT IS DIPHTHERIA?

By not a few clinicians the dread term diphtheria is limited to cases presenting only the most marked features of the disease. Severe putrid throat, with false membrane and much swelling, general involvement of the neighboring glands, and severe septic symptoms, are for these men, necessary, to constitute a case of diphtheria. In consequence, particularly if they practice outside of the larger cities, where the disease is always more prevalent, they find diphtheria a rare disease.

But diphtheria, like all the infectious diseases, can and does possess a wide range of severity. In its mildest types, the false membrane is usually limited to the tonsils, and in some instances it cannot be certainly distinguished from follicular tonsillitis. Nevertheless these cases are diphtheria, and are quite as capable as more severe cases of becoming foci of infection. The physician in attendance upon such cases is bound to take cognizance of the possibility of infection, that he may take proper precautions if he goes

into the lying-in room, or makes a surgical operation. The best proof of the real character of the milder cases is found in the sequelæ which sometimes occur. Paralysis of the throat, essentially a post-diphtheritic condition, occurs after sore throats so mild as not to have required treatment, and only remembered when the physician seeks a cause for the paralysis.

Unfortunately, mild cases at the beginning, do not always remain mild throughout the whole course of the disease. Marked extension of the process, with the occurrence of septic symptoms, may come on at any time, and if such a period be waited for, before the diagnosis of diphtheria is made, the golden opportunity is lost. Now that it has been settled beyond all cavil that the false membrane is the place of formation of the poisons which produce all the symptoms of this disease, it is clear that the time for interference is at the beginning of the trouble, and not after great extension of the membrane has made its destruction almost impossible. Therefore the time for diagnosis is early, and the first appearance of a false membrane in the throat, no matter how slight, no matter how mild, is the time to say "diphtheria," and to act accordingly.

Diphtheria should be defined as a false membrane existing upon a mucous or wound surface. This meaning of the term should hold, whatever be the anatomical location of the membrane, or whether it occur primarily or as a complication in the course of some other disease, as scarlatina or typhoid fever, or whatever be the particular bacterial cause of the appearance of the membrane.

The term diphtheria has recently been attacked from another quarter. WELCH and OSLER of Johns Hopkins propose that the term diphtheria shall be reserved for the conditions produced by the Lœffler bacillus, while other processes in the throat characterized by the formation of false membrane shall be denominated pseudo-diphtheria. It does not appear that their diphtheria and pseudo diphtheria differ from each other, except in their etiology; distinguishing clinical differences are not pointed out. With all due deference to the men making this proposition we respectfully submit that such nomenclature would lead to inextricable confusion. The term diphtheria has already attained a definite clinical significance, and if this significance can not

be made to harmonize with recently discovered etiological factors, the necessary change in nomenclature should be applied to the etiological factors, leaving the old term undisturbed in its original meaning. The term "amoebic dysentery" is a good example of this method of nomenclature.

The difficulty already met, with regard to diphtheria, indicates some of the troubles to be met in classification of diseases, with advancement in etiological information. Theoretically, a scientific classification of diseases can only be made upon an etiological basis, but if the etiological classification can not be made to harmonize with clinical differentiation, it will fail of its object.

With regard to diphtheria we plead for its retention as a purely clinical term, to be employed in the sense already defined, and we further plead that all false membranes in the throat shall be recognized as diphtheritic, and treated accordingly.

HABITUAL ENDORSERS OF NOSTRUMS.

The *Western Druggist*, November, states that the same clergymen and women who gave such rose-colored testimonials to the HUBBARD AYER concoction of cocaine in poor sherry, are now among those who are bolstering up the "gold cure" for inebriates. The same journal makes mention of another and stranger incident regarding this same "cure." A physician has begun a libel suit against the proprietor of the fraud. The former addressed a letter of inquiry about the plan of treatment, and was thunderstruck to find himself enrolled among the drunkards who had been cured. This kind of endorsement of nostrums is one habitually used by the receivers of the letters, although not so intended by their authors. When the people begin to "poke fun at" or ridicule a quackish undertaking, its race must be nearly ended.

TURPENTINE IN POST-PARTUM HÆMORRHAGES.—When ordinary means have failed a piece of linen saturated in turpentine, introduced into the uterine cavity and compressed against its walls, excites contraction of the womb and instant arrest of the bleeding.—*Ex.*

NECROLOGY.

James Watt, M.D.

[Memorial minute respecting our late Fellow, Dr. James Watt, read at the November meeting of the Kings County Medical Association, Brooklyn.]

James Watt, M.D., a member of this Association since 1887, departed this life September 10, 1891, in his forty-eighth year. He was a Scotsman by birth, having had Aberdeen for his natal town. He was born in 1844. When 5 years old he was brought, with other members of his family, to this country, and to this city about two years later. He was here educated, and entered upon the practice of pharmacy as a preliminary to taking his medical degree. He attended lectures at both Bellevue Hospital Medical College and the Long Island College, receiving his diploma from the latter school in 1866, when he was 22 years old. After his graduation he made a visit to Scotland, but did not there undertake additional medical courses, as has been stated, since his stay abroad was only for a short time. He made his home for life in the Southern District, living for the twenty or more years of his professional activity chiefly on Court, Union and Carroll streets. His last abiding place, on the corner of Court and Carroll streets, has been, for that part of the city, one of the best known medical situations for four decades. In 1870, Dr. Watt joined the county organization, and about five years later was chosen Surgeon to the Southern Dispensary. He had a strong predilection for political life, and was measurably successful in his combinations therein. He served one term in the State Assembly, being elected from a district which commonly went against his party, for he was undoubtedly widely known and very popular. He was not so successful when running before the county at large for the position of Coroner. He held appointive positions in the Department of Health, as Registrar of Vital Statistics, and in the Police Department as Surgeon under two changes of administration. He was partial also to the work of the National Guard, which he entered first as Assistant Surgeon of the Thirteenth Regiment, under appointment by Col. Mason. He served in that capacity eight years, when he was promoted Surgeon of the Fifth Brigade, on the staff of Gen. Christensen. As a practitioner Dr. Watt was diligent, earnest and persistent, so that, with much of inherited Scottish grit and thrift in his mental make-up, he won a large measure of success, in the face of not a few obstacles at the outset of his career. He was a member of the Physicians' Mutual Aid Society, and many other social and professional organizations.

R. M. WYCKOFF, M.D.,

T. M. LLOYD, M.D.

Julius Guenther, M.D.

Some philosopher has said that as man comes unconscious into the world, so, next to the life upon which he then enters, the greatest boon that can be granted to him is to be permitted to take leave of that life unconsciously. The friend whose memory we would here perpetuate was thus favored, having, after a lingering disease, passed away quietly and unconsciously, August 17, 1891.

Dr. Julius Guenther was born in Berwalde, Saxony, in 1827. He came to America in 1853, and continued the medical studies which he had previously pursued at the Universities of Leipsic, Halle and Vienna, graduating at the New Orleans School of Medicine in 1857. He first came to this county in 1859, practicing his profession at Coatsburg for two or three years, then returning to New Orleans, where he remained until 1865. The next twelve years were spent partly upon his farm near Coatsburg, and partly in New Orleans. Coming North for the last time in 1877, he settled in Quincy, and has since been among our most active members. As a man, Dr. Guenther was upright, mindful of his duties as a citizen, and a model in all his domestic relations. As a physician, he was skilful, conscientious and untiring, always a student, loving his profession, zealous for its advancement and jealous of its dignity.

In token of its appreciation of the worth of its late President, Dr. Julius Guenther, in all these relations, in recognition of the loss it has sustained, and with profound sympathy for the bereaved kindred whose loss is still greater, the Adams County Medical Society places this memorial minute upon its records.

CHARLES W. ROOK, M.D., Sec.

Quincy, Ill.

B. S. WOODWORTH, A.M., M.D., died September 10, 1891, at the age of 72 years and 7 months. For over fifty years he had been actively engaged in the practice of medicine in Fort Wayne, Ind., and for all these years had been standing at the head of the profession as a highly cultured, conscientious physician. In fact, he was far above the average of his day, both in literary and medical attainments, and was a most valuable man in the community. That he was tenderly beloved by his professional brethren was demonstrated on the day of his funeral, when all in the city were present. The citizens, in fact the entire city, mourned when his death was announced; how could it be otherwise, a beloved physician, in whom all had confidence, had died. He had been honored by being elected President of the Indiana State Medical Society, and at various times had been President of the County Medical Society.

No physician was ever more highly honored and respected by all classes of citizens and the profession than Dr. Woodworth, and his memory will be cherished for many years.

LEVI IVES, M.D., formerly a member of this Association, departed this life at his home in New Haven, Conn, November 29. He was a native of that city, born there in July, 1816. His father, Dr. Eli Ives, was President of the Association in 1860, and forty years a professor in Yale. Dr. Levi Ives obtained his medical education under his father, and at Bellevue Hospital, New York. The high hereditary name of his family in medicine was honorably sustained by him for nearly half a century, but only as a practitioner and not as a teacher, as several of his kindred have been. He was a consultant physician to the City Hospital, and prominent in his local scientific associations. His son, Dr. Robert Shoemaker Ives, succeeds him upon the staff of the New Haven Hospital. His final illness is ascribed to chronic renal disease.

THE ACTION OF TUBERCULIN UPON THE EXPERIMENTAL EYE TUBERCULOSIS OF THE RABBIT.

Report from the Institute for Infectious Diseases in Berlin.

BY PROF. W. DOENITZ.

Contrary to the negative results of Baumgarten, the author said, in his report before the Society of Charité physicians, that he is now in a position to demonstrate healed tubercular processes accomplished with tuberculin, and which have been heretofore considered as impossible. The author then demonstrated, in the eyes of a number of rabbits, tubercular processes established by inoculation, both with pure cultures and with tubercular tissues, in various stages, from that of the first irritative reaction, occurring about the middle of the third week, to that of the complete cure, the latter resulting in from three to four months, the eye retaining its function as a visual organ.

In the early part of the treatment with tuberculin, the tubercular process is hastened, cloudiness of the cornea and pannus developing rapidly, whereas in the eye of the control animal, the process is slower, with, however, early necrotic processes at the seat of puncture and rapid perforation, this necrosis not occurring when tuberculin in gradually increasing doses was administered. It is immaterial whether the treatment is begun immediately after inoculation, or at a time when true tubercle had been formed. The administration of the product obtained by Klebs from Koch's tuberculin was attended with only temporary improvement; the eyes were eventually lost. The same dose of the unmodified tuberculin, and continued without increase, also failed to produce good results.

The conclusions are:

1. The tuberculin is a sure curative agent for the experimental tuberculosis of the eye of the rabbit.
2. The tuberculin shows its curative effect only after true tubercle can be demonstrated.
3. The first effect of the tuberculin is a transient but severe irritation of the eye.
4. Under the continuous action of the tuberculin, all irritation in the eye subsides.
5. When, before beginning of the treatment, deep-reaching destructive processes have not occurred, the cure results in retention of the visual functions of the eye, otherwise, atrophy results.
6. To a cure it is necessary that the tuberculin be given in increasing doses, and the continued maintenance of a not too slight reaction is essential.—*Deutsche Medizinische Wochenschrift*, November 19, 1891.

BOOK REVIEWS.

HUMAN MONSTROSITIES. By BARTON COOKE HIRST, M.D., Professor of Obstetrics in the University of Pennsylvania, and GEORGE A. PIERSON, M.D., Professor of Histology and Embryology in the University of Pennsylvania, Philadelphia. Large folio, 13 x 17 inches. In four parts, to contain about 150 pages of text, with 39 full-pages photographic plates from nature, and many engravings. Price per Part, \$5. Limited Subscription Edition. Part I, pages 1-88, Plates i-vii. Philadelphia: Lea Brothers & Co., 1891.

This work is one of the most interesting and artistic contributions to the science of medicine which we have ever seen. It treats of a subject upon which very little of a systematic character has been written. The science of teratology is more than a novelty to the scientific physician. A knowledge of it is of great practical importance to the general practitioner, and to the obstetrician is a *sine qua non*. It would seem that no treatise upon human anatomy could be complete without a more or less comprehensive and systematic discussion of this highly interesting and scientific subject, yet where can we find an anatomy which devotes any attention to this subject, or, at least, which devotes space enough to enable the practitioner to acquire even a fair understanding of the various monstrosities which the human species is prone to develop. As far as English literature is concerned, this is the only work which has so far appeared which is at all systematic or scientifically comprehensive. The works of Förster, Ahlfeld, and particularly that of Geoffroy Saint Hilaire are classics upon this subject, but unfortunately are inaccessible in the original to English speaking and English reading physicians.

In preparing the material for the work before us, the authors did not find it necessary to draw upon European material to any extent. The Wistar and Horner Museum of the Pennsylvania University contains a very valuable and varied collection of human monstrosities, some of the specimens being exceedingly rare.

The illustrations in Hirst and Pierson's work are faithful photographic reproductions of the original, and from an artistic standpoint can hardly be excelled. The type

is clear and beautiful, the text comprehensively descriptive, and free from verbosity. The authors have not attempted profuse padding, and their language has sufficient rhetorical elegance to render its perusal pleasurable. We shall await with considerable interest the appearance of Part II.

THE ENCYCLOPÆDIC MEDICAL DICTIONARY. By FRANK P. FOSTER, M.D. Part viii, Gym-Jab. Pp. 1793-2040. New York: 1891.

This installment of Dr. Foster's great work completes the second third of its promised issue. True to the history of every work of reference that was ever undertaken, this book becomes more and more incompressible as it progresses, and we begin to wonder how the editor will be able to stow away the remaining two-thirds of the alphabet in the four parts yet to issue.

The reputation for scholarship and learning—two different commodities, by the way—earned by the compilers of the earlier parts, is abundantly sustained by the issue just received. We have had occasion to consult the words *hernia*, *hyoscine*, *iridectomy*, *hæmatin*, *jaborandi* and *hospitalism* and the definitions found under them have satisfied us that they are based on "independent reading." The collateral sciences have not been neglected, but they appear to occupy less space than in the earlier parts; as for example, *hygometer* and its congeners occupy but sixteen lines, while *barometer* was allowed nearly two pages, inclusive of its illustrations. The temptation to shorten up in the use of illustrations, will be inevitable as the page-space dwindles, but these woodcuts, unless they are very good, are out of keeping with the fine text that is provided. The subscribers will not feel any disappointment if only the best ones are inserted. It is almost unnecessary to add that the value of the work increases in almost a geometrical ratio as the later parts come along. Now is a good time for those who have a prepossession against taking books by subscription to break away from prejudice, and take unto themselves a book which has more of usefulness in it than any completed medical dictionary they can procure.

SELECTIONS.

THE BICHLORIDE OF GOLD TREATMENT FOR INEBRIETY.—The attitude of the medical press toward the Keely treatment is very properly that of agnosticism. The general opinion seems to be that the Keely cure will go the way of many other much vaunted specifics, and after the reaction from the stimulating effect of faith will ultimately come the disappointment of relapse.

The so-called cure has brought to public attention the attitude of the medical profession towards doctors who keep secret discoveries made by themselves, or secure patents on such, or otherwise seek to make their discoveries a source of exclusive profit to themselves.

The doctors call this quackery and refuse to have relations with men who practice it, and for this many persons regard the profession as narrow-minded.

But the doctors are right. It is not in their own but in humanity's interest that they hold each other to this rule of ethics. It is the doctrine of the profession—as old as Galen—that the first duty of the doctor is to hu-

manity, that his learning and his skill belong to mankind, not to himself. Hence it is held to be his obligation to give to the profession, for humanity's benefit, whatever discovery or device he may make tending to the saving of life or the mitigation of suffering.

To this, moreover, every physician upon graduation makes oath of allegiance, so that the doctor who violates the ethical rule disregards his own oath. Even the pretension of such an one as to his discovery must be taken as that of a man unworthy of confidence.

The rule is a generous, not a narrow minded one. It has its source in a high and unselfish conception of duty, and its rigid enforcement is a matter of true morality as well as professional ethics.—*Medical Age*.

AN APPARATUS for the production of local anæsthesia in the mouth, pharyngeal and other cavities, has been brought out by Weisendanger, at Hamburg. This consists of a double tube well protected by a horn or gum-elastic handpiece so as to prevent the warmth of the hand interfering with the production of the cold. Through the inner tube compressed carbonic acid or ammonia is introduced into a small leather bag, in which it expands, producing intense cold, and escaping therefrom by means of the outer tube. Attached to the handpiece above mentioned is an additional sheath which protects the tube from the mucous membrane of the cavity at the depth of which it may have to be applied.

IDENTITY OF THE BACILLUS OF EBERTH AND THE BACILLUS COLI.—At the *Académie de Médecine*, Messrs. Rodet and Roux, of Lyons, communicated the results of their examination of the bacillus of Eberth and the bacillus coli. The conclusion to which they came was that these two bacilli were in reality one and the same microbe, presenting itself in various forms according to the conditions of the organisms in which it was developed.

POST-MORTEM APPEARANCES IN THE BRAIN AND INTERNAL EAR IN A CASE OF PERNICIOUS ANÆMIA (*Annales des Maladies de l'Oreille*).—J. Habermann contributed a communication giving the appearances which he found *post-mortem* in the brain and the internal ear in a case of pernicious anæmia in which a prominent symptom had been vertigo with deafness. There were hæmorrhages of the meninges and brain substance, also extensive hæmorrhages in the semi circular canals. The hæmorrhages were all due to diapedesis rather than ectasis. The author hesitates as to which lesion to attribute the vertigo.

THE SUCCESSOR TO PROFESSOR CARL BRAUN has been elected in the person of Dr. Friedrich Schauta, of the University of Prague, the author of the "Manual of Operative Midwifery" and numerous lesser works. He will occupy the chair of midwifery and conduct the first obstetrical and gynecological clinique.

ARTIFICIAL CORNEA.—The *Berlin. Klin. Wochenschrift* publishes a seventh case of transplantation of cornea by Professor V. Hippel, of Königsberg. Cocaine applied, the non-transparent part of the cornea, down to the membrane of Descemet, was cut by a little trephine and carefully removed. By the same means a similar piece was excised from the whole thickness of the cornea in a young rabbit, and transplanted to the eye of the patient. It filled the wound, and was on a level with the rest of the cornea. Iodoform was applied, and both eyes were bandaged. In six weeks the patient was discharged with a completely transparent cornea.—*Medical Age*.

CAMPHOR menthol will be found efficacious in pruritic and herpetic and eczematous eruptions. It promptly allays local irritation, contracts the capillary vessels and exsanguinates the part.

WHEN IS A SEA VOYAGE APPROPRIATE?—*The Sanitarian* offers the following advice on the subject:

Never send a patient to sea who is compelled to live on a limited diet, unless he can take the requisite food along with him, a ship being the poorest place in the world where to obtain any special article of diet. More ground will be lost by patients under such circumstances, in one week, than can possibly be regained in many months following, on shore, even under the most favorable conditions. There cannot be the slightest doubt in the world that a sea voyage may be, and is, beneficial in a great majority of chronic cases, but it should be a voyage chosen for its especial adaptability to the case in question, and the climate, class of steamers, food, etc., should have the careful consideration of the family physician before he sends his patient on a month's voyage by water, for a lack of information on the physician's part may mean no improvement to the patient, and may mean death, whereas positive knowledge would insure improvement.

MISCELLANY.

DR. PAUL F. MUNDÉ has retired from the editorial control of the *American Journal of Obstetrics*. Dr. Brooks H. Wells is his successor.

CHICAGO MEDICAL SOCIETY, D. R. BROWER, M.D., President.—A regular meeting will be held at Washington Hall, 70 Adams street, on Monday, December 21, 1891, at 8 o'clock P.M. Papers will be read as follows:

1. "Medical Diagnosis of Diseases of the Stomach," by Dr. J. B. Herrick.
2. "Medical Treatment of the Diseases of the Stomach and Duodenum," by Dr. Frank Billings.
3. "Surgical Diagnosis of the Diseases of the Stomach," by Dr. Weller Van Hook.
4. "Surgical Treatment of the Diseases of the Stomach," by Dr. Nicholas Senn.

The discussion will be opened by Drs. N. S. Davis and Ludwig Hektoen.

JUNIUS C. HOAG,
Secretary.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from December 5, 1891, to December 11, 1891.

Capt. Arthur W. Taylor, Asst. Surgeon U. S. A., having been found incapacitated for active service, is granted leave of absence until further orders, on account of disability.

First Lieut. Paul Shillock, Asst. Surgeon U. S. A., is granted leave of absence for fifteen days.

Capt. William E. Hopkins, Asst. Surgeon U. S. A., resignation has been accepted by the President, to take effect April 5, 1892, and granted leave of absence to include that date.

Major Passmore Middleton, Surgeon U. S. A., having been found incapacitated for active service, by reason of disability incident to the service, is, by direction of the President, retired from active service.

Capt. Walter W. R. Fisher, Asst. Surgeon relieved from duty at Ft. Assiniboine, Mont., and ordered to Ft. Columbus, New York Harbor, for duty at that station.

First Lieut. Charles E. Woodruff, Asst. Surgeon, is relieved from duty at Ft. Missoula, Mont., and ordered to Ft. Assiniboine, Mont., for duty at that station.

First Lieut. James D. Glennan, Asst. Surgeon, granted leave of absence for one month, with permission to apply for one month's extension.

Capt. Henry G. Burton, Asst. Surgeon, ordered to report to the President of the Army Retiring Board, at Los Angeles, Cal., for examination by the Board. On conclusion of his examination, will return to his station, San Diego Bks., Cal.

Major Julius H. Patzki, Surgeon U. S. A., will report in person to the President of the Army Retiring Board, at Ft. Leavenworth, Kan., for examination by the Board. By direction of the President.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending December 12, 1891.

Asst. Surgeon Lewis Morris, detached from the Navy Yard, League Island, and to the receiving ship "St. Louis," at that yard.

Asst. Surgeon H. N. T. Harris, detached from the receiving ship "St. Louis," and to the Navy Yard, League Island, Pa.

ORIGINAL ARTICLES.

THE PRIVATE CARE OF EPILEPTICS.

*Read before the Massachusetts Medical Society, Suffolk District,
October, 19, 1891.*

BY LUCIUS W. BAKER, M.D.,

SUPERINTENDENT RIVERVIEW SANITARIUM FOR NERVOUS IN-
VALIDS, BALDWINVILLE, MASS.

In nearly every community will be found one or more individuals who are suffering from that peculiarly distressing disease known as epilepsy. Niemeyer places the proportion of such cases at six in every thousand.

In this disease the autopsy and the microscope have afforded us but little satisfaction. There seems to be no fixed and constant pathological lesion attendant upon the wide assemblage of symptoms classified under the name of epilepsy. The few histological changes which have been reported are, it seems to me, to be considered as results rather than causes of the disturbance.

But if our knowledge of the actual pathological changes occurring in epilepsy is vague and unsatisfactory, the results of experiment and clinical observation are more gratifying, for the researches of J. Hughlings-Jackson, Gowers and others have furnished us with a more satisfactory explanation of the phenomena of the disease than any we have heretofore possessed.

According to these observers an epileptic paroxysm is due to a sudden and excessive functional activity of the gray matter in some portion of the brain. This rapid action of certain nerve centres, with its resulting phenomena, is called a "discharge," which may commence in any part of the gray matter of the brain, remain confined to the portion in which it originated, or may extend to and involve other portions; hence the wide variety of manifestations which constitute an attack. There may be, for example, a momentary loss of consciousness, a slight incoherence, or mental blank, without muscular spasm, or the attacks may be of a convulsive character, involving few or many muscles; auræ of the greatest variety may be present, or the patient may have no warning whatever of an approaching seizure, while not infrequently the attacks are preceded or followed by more or less mental excitement.

This rapid liberation of energy in the nervous centres, giving rise to an epileptic paroxysm, may be due either to a sudden diminution of inhibitory power, or to an excessive and rapid generation of nerve force within the cells affected. It is, however, important to remember, that the primary and essential element in the production of a "discharge" is the presence of an inherent instability of certain portions of the gray matter within the encephalon, which may be due to heredity or other predisposing causes, some of which are beyond our power of detection.

The manifestations of epilepsy are such as to usually incapacitate the individual from engaging in the ordinary occupations of life, and not infrequently compel him to become a useless burden upon his friends or upon society. In the vast majority of cases epileptic attacks leave a permanent impress upon the cerebral structure; we seldom meet with a case in which careful study will not detect some evidence of mental impairment. Many terrible crimes have been committed during an outburst of epileptic mania, while all degrees of mental degeneration will be met with down to complete idiocy of dementia.

An epileptic is not only exposed to all the dangers resulting from a sudden loss of consciousness; he may also, in a greater or less degree, be mentally defective. He has therefore a double claim to be dealt with according to his peculiar requirements. But, singular as it may seem, when we consider the nature of his malady, these claims have, in this country at least, been almost entirely ignored.

At present the only place, to my knowledge, in which an epileptic can be received for care and treatment is in institutions devoted to the care of the insane, and these are obviously unsuitable for this class of cases. Hospitals for the insane are intended only for the treatment of mental diseases. This is their special office. They were never designed for the treatment of epileptics, any more than for the treatment of dipsomania, and it is a manifest injustice to send an epileptic to one of these institutions. Such a course cannot but be detrimental to both classes.

During their freedom from attacks, epileptics resent the companionship of the insane, while the latter ought never to witness the wild contortions

or to hear the piercing cry of an epileptic seizure. *So far as the care which society extends to its afflicted members is concerned, a man had better be insane than an epileptic.*

I am well aware that the medical profession generally entertains a gloomy view with regard to the results of the treatment of epilepsy, and that the opinion prevails that it is an incurable disease. Granting for a moment that this is correct, is not the same equally true of many other diseases, the severity of which we are able to relieve materially by judicious care?

One advantage, among others, which the long-continued hospital treatment of epilepsy will secure, is the administration of the necessary remedies with unfailing punctuality, and the proper regulation of the diet, two important factors in securing a favorable result. The difficulty of securing these necessary conditions will account for many failures in the treatment of this disease in private practice. I have frequently had patients remain entirely free from attacks during a hospital residence of months, but have known the seizures to return soon after their removal to home surroundings.

In an interesting paper¹ read before this Society last December, Dr. W. N. Bullard called attention to the lack of proper facilities for the care of the pauper epileptics of Massachusetts, and urged that separate provision be made for this class of patients. The subject was quite fully discussed at the time, and at the last annual meeting of the Massachusetts Medical Society, a committee was appointed to present the matter to the Legislature. Should any action be taken by the State, I presume that certain cases of epilepsy, now in the State hospitals for the insane, will be separately provided for, as will also those cases now in institutions for children, who have reached adult life.

Several years ago I became interested in the care of epileptics in connection with a small charitable institution for children, which was then in its infancy, and which was one of the first in this country to provide special accommodations for this class of patients. At that time we received a few patients who were beyond the age of childhood, and also foresaw that a difficulty would arise within a few years as to what should be done with those who, coming under our care as children, should remain until they became adults. This is now proving a serious problem to the managers of the same institution, whose capacity has since been largely increased. Their last report says, "that of the reported number of cases of epilepsy a very large proportion is above the age of fifteen years. As a rule, parents prefer to keep their own children if possible, and while they are young it is generally possible; but after they get to larger years the

difficulty of managing them becomes more than the family is willing to undertake, or the friends to permit. They are then reported as epileptic and a place of asylum is sought for them. The larger number of our applicants is of this class. The number is a growing one, and the time is near when provision must be made for the hospital care of a considerable number."

The older cases of epilepsy are manifestly out of place in an institution for children, but as yet there is no other place to which they can be sent, except the insane asylum or almshouse. As the matter of providing for adult pauper epileptics was carefully considered last December, it is not necessary for me to discuss it further at the present time. I desire rather to call your attention briefly to the desirability of also providing suitable accommodations for epileptics whose friends are able to pay a moderate sum for their support.

No one who has not had practical experience with such a patient can appreciate the continuous strain which an epileptic occasions in the family to which he belongs. The constant liability to disastrous falls or injuries, the mental hebetude, the irritability, the peevishness, the unearthly cry, the distorted features, the wild contortions are a continued source of care and anxiety which few can long endure without injury.

In the ordinary home, an epileptic can seldom obtain the care which his condition requires. The wealthy can, of course, provide separate apartments and special attendants, but even these often prefer accommodations elsewhere. I have had such cases under my care in the past, and within a few weeks I have had a most urgent request to receive an epileptic patient, whose parents are both able and willing to pay well for his care. Similar letters come to me from time to time showing that there is a demand for such accommodations even among those who are amply able to care for their friends at home.

But the burden rests heavily upon those in moderate circumstances, whose means will not permit their entrance into a strictly private institution even if they could be received. Such cases are willing to pay all and even more than they are able.

I doubt not that there are many cases of epilepsy among the middle classes, who for their own and others' sake ought to be taken care of away from home, but whose friends will not allow their removal to any strictly charitable institution for epileptics, did one exist.

The scale of expenditure demanded in the private asylums is such as to place them beyond the reach of people of moderate means, and even those whose circumstances will enable them to command the resources of these institutions are debarred from entering them on account of the nature of their disease, for epileptics ought not

¹ Boston Med. Journal, vol. cxxiv. p. 25; discussion, p. 36.

to be associated with nervous or mental cases, in the same institution, or even within the same grounds. I speak from experience, as I once had a cottage filled with mild private cases of epilepsy, but was obliged to send them all away, on account of its close proximity to another building in which there were other nervous patients.

It seems desirable, therefore, that these cases should be provided with suitable accommodations away from other patients, and at a sufficient distance to prevent annoyance to the community in which they may be placed. The buildings should be arranged with special reference to the peculiar requirements of those who are to occupy them. A one-story structure will be preferable, and the house and its furnishings should be constructed so as to diminish as far as possible, the liability to injury from falls.

I can see no serious obstacle to the establishment and maintenance by benevolent people of small institutions for the care and treatment of non-pauper epileptics. Such an establishment in my opinion should be entirely free from State control. It should be managed by a board of trustees as a private institution, with nothing in its name to characterize its special work.

The building should be located in the midst of ample grounds, without neighbors in its immediate vicinity, and provision might as well be made for a variety of light occupations, as during the intervals between the attacks many epileptics are able to work, and are much better for being occupied. The house should also be furnished with all the comforts to be found in the homes of people of moderate means, so that the home-like atmosphere may be continued as far as possible. If suitable rooms were provided I have no doubt they would soon be occupied by those able to pay a large sum for their accommodations, thus diminishing the expenditure of the institution.

In brief, I would furnish this class of epileptics as I would many of the milder cases of insanity, with all the comforts of a well-ordered home; with trained attendance and with skilled medical care at a price within their limited means.

I am well aware from personal experience that such accommodations will be quite expensive. To carry on such an institution successfully the amount received for board must be largely supplemented by the contributions of benevolent people able and willing to aid such an enterprise. An endowment fund will be of the first importance, and this would doubtless be secured as soon as the necessities of this class are fully understood.

It is our pride and boast that Massachusetts never turns a deaf ear to the cry of the sick and the suffering, that no worthy enterprise lacks support among us. I trust that the time is not

far distant when to our long list of benevolent enterprises will be added one or more devoted exclusively to the treatment of epilepsy.

SOCIETY PROCEEDINGS.

Massachusetts Medical Society, Suffolk District.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

The meeting was called to order Wednesday, October 21, 1891, at 8 o'clock, by the Secretary. The first business was the election of a chairman. Dr. E. G. Cutler was unanimously re-elected to that office.

Lucius W. Baker, M.D., Superintendent River-view Sanitarium for Nervous Invalids, Baldwinville, Mass., read a paper on

THE PRIVATE CARE OF EPILEPTICS.

(See page 983.)

Mr. F. B. Sanborn, formerly Inspector of State Charities, opened the discussion.

I have been long acquainted with Dr. Baker and with his interest in this subject, the care of epileptics. I do not know whether Dr. Baker attempted to give any estimate of the number of epileptics in Massachusetts. I have never been able to arrive at any estimate. The census does not give any estimate. Within a few days, however, expecting to listen to Dr. Baker here, I endeavored to look up the matter. I went to the different boards in Boston, and I find it is not in the possession of any board or bureau in the State, and can only be arrived at by estimate. I suppose we have at present in Massachusetts not less than 8,000 insane and idiotic persons. The census may not show so large a number. Now of those two classes a definite proportion, not less than 5 per cent., is always found to be epileptic. I estimate, therefore, that if we have 8,000 persons mentally affected in Massachusetts, we must have from 400 to 800 epileptic persons among them, in the later stages of epilepsy ordinarily, where the mind has been seriously and oftentimes permanently affected. There must be at least double this number, I suppose, of persons where epilepsy has not yet reached this stage. It may never get so far. I therefore suppose that we must have in Massachusetts from 1,200 to 2,000 persons of the epileptic class. This number, probably, is constantly increasing as our population increases.

Now the State has made no provision, separate from the care of the insane, for this class of persons, except in the small institution which Dr. Baker founded at Baldwinville, and which contains at present something like eighty epileptic

children in the hospital cottages. Most of these are persons belonging to the pauper class; that is to say, come from families not able to pay even the small sum which is required in the institution for the board of the children (amounting to about \$3.25 per week), and therefore are supported either by the State or by the gifts of benevolence. There are some supported in the almshouses, etc. There is, in addition to this class of the epileptic poor that must be supported by the taxpayers, a considerable class of persons whose friends are able to support them, but have absolutely no place to which they can be sent, where they can receive special attention apart from other patients, which epilepsy requires. That is a serious deficiency in our charitable system. It is one in which Massachusetts is not alone by any means. There is no State in the Union, I think, which maintains a special institution for epileptics which is sufficient to receive the epileptic persons of that State, and few of the countries of Europe have any such institution. There are several excellent institutions for epileptics in Europe; but in Massachusetts we certainly are able to support, and I think the munificence of individuals will be ready to organize, an institution for persons of small means, who can afford to pay the expense of placing their relatives in such an asylum. It would be necessary, I suppose, to begin in a small way, and probably it would be found desirable not to increase the number of inmates of such an asylum to anything like the number treated at Bielefeld. That would be my own view of the subject. The public authorities will provide in their own manner, and they will constantly improve, the treatment of their own cases. They will provide for the epileptic poor; but the other class will be compelled, until some such asylum is established, to be sent either into families, where oftentimes they can be properly treated (but by no means the whole number can be so disposed of), or else into asylums for the insane, where they not only very much disturb the treatment of the patients who properly belong there, but fail to receive the treatment which they themselves require.

The case of Barber, reported in the *American Journal of Insanity* by Dr. Wise, which came under my personal observation, illustrates well the dangerous homicidal tendencies of some epileptics.

I suppose there is hardly a person in this community who would be less suspected of epilepsy than Richard Barber was for months and years before this homicide; and yet he, being subject to a species of latent epilepsy, seizures occurring only in the night, had fallen into the dangerous and distressing condition which epilepsy sometimes produces, that is homicidal fury, which will cause an assault upon any person within reach of the epileptic. He had killed his two

best friends in America, and when it was over he was unconscious of the deed.

This is one of the dangers to which any community is exposed which makes no provision for its epileptic subjects.

Mrs. Mary A. Livermore: While Mr. Sanborn was talking, I have been running over in my mind and trying to make a *résumé* of the number of persons I have known who have been afflicted with epilepsy in the last thirty-five years. I am able to recall forty-two. The results of my observation have convinced me that this affection is much more common than one would think. I have not found that a very large proportion of epileptics are connected with the very poor people, or those whose lives have been exceedingly barren of comfort or nourishment, or who have been very much vitiated by bad habits or bad methods of living. Almost all the epileptics whom I know are so situated that they could pay for care in an institution, if there were one in which they might be received. They could not pay fabulous prices, but could pay *something*. Of the eighty epileptics now in the hospital at Baldwinville, I am informed that forty pay *something*. So that it does not seem as if it would draw so very largely on the funds of those charitably disposed if this matter were attended to.

Everything that has been said concerning the difficulty of taking care of epileptics in the *family*, is so true that it cannot be overstated. It is not a possible thing, unless one can set apart rooms for the epileptic, and have one person in charge of him constantly. I have found that in cases where the epileptic could be absolutely under control in regard to habits of rising and retiring, food, etc., the horror of the thing could be mitigated, and the person made companionable and attractive in the family. I believe the frequency of attacks may be greatly diminished by strict attention to food, habits, etc.

Mrs. Livermore described at length an institution for epileptics in London, in which the different classes of epileptics received treatment suited to their condition.

Dr. T. W. Fisher: When the subject of a new hospital is broached, the questions always arise, Where are the patients coming from? Is there a sufficient number of patients of that kind to avail themselves of the new institution? Perhaps these are not difficult questions to answer, for I do not know of any hospital so large that it could not be filled in six months.

The question of epilepsy is interesting, like everything connected with the subject. I was unable to get any facts in regard to the number of epileptics in Massachusetts; neither could I find directly the number of epileptics in our State hospitals in Massachusetts. The statistics deal with admissions only, and not with the number of resident epileptics. The number of epileptics

in my own hospital, which contains 435 patients, is twenty-seven, or about 6 per cent., and 6 per cent. of the number in the State hospitals would be about 300. The number admitted to the State hospitals for eleven years I find to be 731 cases of epilepsy. In that number 17 recovered and 231 died, showing an extremely high death-rate, and an extremely light percentage of recovery. Perhaps some allowance is to be made, because recovery from epilepsy is rather deceptive. The United States census for 1880 shows 74,184 insane in the United States, of which 6,842, or 9 per cent., were epileptic. In 1880 I find that there were 281 epileptics in the State institutions, or 6 per cent. of the number of insane.

In Berlin the number of insane in the city has increased very rapidly, much more so than the population; and the number of insane in the hospitals of Berlin, public and private, in 1890 was 22,659, including idiots and imbeciles and epileptics. Of this number 494 were epileptic, showing 19 per cent. against six per cent. in this State, so that our proportion of epileptics in insane hospitals is much less. At Bielefeld, which I visited, I saw institutions for the treatment of epileptics containing 100, who are mostly pauper epileptics, and who are taken care of in a most suitable and creditable manner. I saw one immense dormitory containing nearly 100 epileptics, having beds about twelve inches high, so that the person could receive no injury by falling out of bed at night. That ward was under constant surveillance during the night, and aggravated cases were at once removed to the adjoining sick-ward. But the number of epileptics in Berlin has increased so rapidly, as well as the insane, that they are about to build a separate colony hospital for about 600 epileptics. This meeting is not especially concerned with that class of epileptics, but the statistics may be of some interest. The increase of insanity in Berlin and Germany, which is far beyond that of the population, is also the same increase as seen in the United States. In 1881 the number of insane in the United States in hospitals was fixed at 56,205, in 1889 the number was 97,534, an increase in nine years of about 75 per cent., while the population has increased 25 per cent.

There is no doubt about there being enough epileptics of the class mentioned, in the State, to fill any hospital that the benevolently inclined are likely to erect. Being connected with a public hospital, I see fewer of the cases of epilepsy of this sort, than physicians in practice outside; and I do not imagine that this new institution would make any great drafts on the State hospital or city hospital for insane. The cases that go to those hospitals are generally the long-standing cases in which the mental symptoms are very pronounced, and the great majority of them also are from the non-paying class.

I now and then see cases in private practice which would be good subjects for hospitals of that sort.

Dr. Baker did not speak of one important point, and that is the legal status of patients in an institution of the kind he described. The epileptics in an insane hospital are all classed as *insane*, can be detained and controlled as if they were insane, and in these hospitals in Germany the status is the same.

Although these hospitals might be very readily filled, the population, I fancy, would be somewhat fluctuating and changing. An adult epileptic is apt to be very self confident, and make very light of his disease. While he might for a time subject himself to treatment in an institution, there would be the probability that after a shorter or longer time he would insist upon going at large. He would dislike the restraint and confinement of an institution, no matter how pleasant and homelike a character it might possess; and I think, to give such an institution the highest value, the patients ought to be committed as they would be in any private institution for the insane. There is no doubt that such an institution would do great good.

Epilepsy, if curable at all, is curable in the very early stages and in the earliest years and months of the disease, and it would be at that early period that the treatment in such an institution would be of most value. The prospect of cure, however, in any stage of the disease is not brilliant, I must admit; but the benefit to be derived by prolonged care and attention is exceedingly great. Not only is the epileptic very much benefited, but the community and the family are protected from the evils that are consequent upon this condition.

Dr. J. J. Putnam:—I came here fully impressed with the very great importance and difficulty of this problem, and not at all prepared to offer a solution of it. I feel that the subject is a very large one, and I do not think that even yet we have entirely covered it. There are certain points on which I suppose we shall agree. First, we all should admit, I think, the great desirability of such an institution as Dr. Baker spoke of for pauper epileptics, since they are a great drain on the happiness and well-being of the families in which they live. Then comes the question of the class of the well-to-do patients. It seems to me the case is quite different, and we are obliged to individualize very much more largely. Dr. Fisher alluded to two points which seem to me of great importance. In the first place, that we should have a right to detain these people so that we might be able to protect the community from such persons as Mr. Sanborn has spoken of.

I have been treating these patients at an outpatient department for twenty years, and I know of many cases of epileptics who live at home hap-

pily and support themselves. But supposing persons could not be detained the greater part of their lives in such an institution, they might be kept long enough to ascertain what for them was the best treatment, and their friends and relatives could be urged to carry it out. I agree that the hygienic treatment is by far the most important.

I think such a hospital would be of great service for purposes of study of this disease. When it comes to the life-long separation of such patients from their families, the difficulties become much more manifest. It is doubtful whether we have the right to expose other epileptics to the danger of homicidal patients.

Although children could be made pretty happy in such an institution, it is very doubtful whether adults could be easily made happy in such a place, and I think we are bound to consider their welfare as well as that of their friends. Most epileptics are to a great degree ignorant of the severity of their attacks. In such an institution as this they would have these attacks constantly before their eyes and it would add greatly to their sufferings.

It seems to me, although such an institution might be very useful, that it should be gotten up, not on the plan corresponding to the colony system, but on the plan of the boarding-out system, which has worked so well with children difficult and hard to manage. I think it would be possible to find a considerable number of first-rate homes where epileptics could be taken and kept almost singly, and at the same time the advantages of this mode of treatment over that in the hospital, would be, so far as the patients are concerned, very great.

Dr. Morton Prince:—I am very glad to have an opportunity to endorse the views of the reader of the present paper. It seems to me the need of a hospital of this kind is a self-evident proposition. It seems a most extraordinary fact that while provision has been made for people suffering with almost every other disease, no provision, public or private, has been made for the epileptics. The deaf, dumb, blind, and even persons with nervous prostration, now have a hospital; but the epileptic has nowhere to lay his head. The necessity for such a hospital seems to be shown by the fact that in other countries, on the Continent particularly, they have provided hospitals for epileptics, although not for the particular class to which Dr. Baker refers. I have made attempts to ascertain the number of epileptics in Massachusetts, but they have been unsuccessful. I had the curiosity to see how many cases were treated at the City Hospital in the course of a year. I found that in the course of one year forty-one patients applied there with epilepsy. The Massachusetts General Hospital does not publish in tabular form the diseases treated there; but if we assume that the same

number apply there, and a similar number at the Dispensary and the Carney Hospital, that would be 120 a year at the different hospitals of the city. Of course, that is a mere estimate; so that, as the life of an adult with epilepsy is not particularly shortened by the disease, in the course of ten years 1,200 epileptics would accumulate in the community. Of course, all these cases would not be appropriate for such a hospital as has been described, but a large percentage would. These figures are interesting as throwing some light upon the frequency of the disease as it is met with.

I have found the treatment at the out-patient service of the hospital very unsatisfactory for more reasons than one. It is very difficult to control the patient, to get him to follow systematically any course of treatment. The treatment is not perhaps very encouraging to them. I think there is no question that the treatment would be far more satisfactory, whatever may be its shortcomings, in an institution of the kind outlined by the reader, than by treatment in private practice or in hospitals. I think that an institution should be arranged on very economical principles. The cost for patients should be low, not over that which now obtains in most of our general hospitals, about ten dollars per week. If we estimate that the average patient could pay five dollars per week, that would leave five dollars per week, as the cost of each patient to the hospital. I should rather doubt the advisability of farming them out in the way suggested by Dr. Putnam, in private families. It seems to me the hospital plan or cottage plan would be by far the better system. Of course, that is a secondary matter.

Dr. F. W. Page: I notice that Dr. Baker speaks of epilepsy as generally incurable. I am aware that a great many physicians take a pessimistic view in regard to epilepsy; but I think a great many cases have been cured, and a great many so far improved as to be useful to themselves and to their families. When I say *cured*, I speak it advisedly. Some patients may not have attacks oftener than once in six months, some once in a year. I can recall cases of epilepsy which have been cured, and have now remained so for many years.

There will always be difficulty attending the getting at the exact proportion of epileptics in the State. It is a matter of serious import to the family. A great many do not like to have it known that they have an epileptic in the family. In the establishment of a hospital it has occurred to me whether it is wise to have it known that it is an *epileptic* hospital, and whether such an hospital might not be joined to some nerve asylum, say, to be considered as a sort of home where patients could have proper care, and not have it definitely known that they had gone to a distinctively epileptic hospital.

The farming out that has been suggested does not seem to me quite practicable.

I doubt whether it would be advisable to have a single hospital for both children and adults. It seems to me, as the State has provided a small hospital for the care of children, that this could be gradually enlarged, and another one could be built for the care of adults.

Dr. Walter Channing: The tendency of modern times has been toward some form of institution-provision for the weak and defective classes, whereby they could receive physical and moral treatment which would improve, or ameliorate their unfortunate condition.

At the foundation of this movement, long before modern times, there existed the necessity that society should protect itself, and hence all kinds of dangerous persons were shut up like wild animals, that they might do no harm. Anything like reformation or moral treatment was of very little moment.

It is only necessary to refer to the treatment of insane persons to see this exemplified. Up to one hundred and fifty years ago the insane can hardly have been said to have had medical treatment. They were supposed to be possessed by evil spirits, and discipline and punishment were resorted to, to get rid of these spirits. At Bethlem (in London) the treatment was terrible, and nothing could have been worse than that at the Bicêtre.

St. Luke's, in London, was founded in 1751; and Letchworth says this was the first English hospital where curative principles were put into practice.

By a curious coincidence, the first step toward giving the insane hospital treatment in this country, was taken the same year, that being the date when the insane department of the Pennsylvania Hospital was established by legislative enactment.

Mr. Letchworth says of the latter: "At this time (1751), punishment in one form or another was, in general estimation, regarded as second only to bleeding, purging and dosing. Even when, in 1783, the philanthropic Dr. Rush resolved to relinquish the chains and whips of his day, he still adhered to 'mild and terrifying modes of punishment,' and on paying a visit to an insane man, deemed it one of the first requisites 'to look him out of countenance.'"

During the next fifty years, as every one knows, rapid improvement in the treatment of the insane in *insane institutions under adequate supervision*, took place, though so much cannot be said of the treatment of the insane in almshouses and in their own homes, as the labors of Dorothy Dix amply testify. Still, up to within the last forty years, we will say, the total number of insane in institutions was not large.

In his admirable report made in 1855 to the

legislature, Dr. E. Jarvis gave the total number of insane in the State as 2,632, of whom 1,141 were in hospitals. Thirty years after, or in 1885, there were 5,263, according to the general census, which was probably not nearly as accurate as the census of Dr. Jarvis. If it had been, the increase would probably have been larger still, say upward of 6,000, as suggested by the Report of the Board of Health, Lunacy and Charity for 1885.

On October 12, 1885, there were 3,862 insane persons in our State institutions, 3,350 of these being in State hospitals. In thirty years it will be seen, there was an increase of over three hundred per cent. in the insane hospital accommodation, the increase in the total number of insane persons being about half that. In the five years since 1885 the number has increased from 3,862 insane persons to 4,701 in our State institutions, a gain of 839 in this short period. The data furnished in a recent bulletin of the Census Bureau show an increase of 73.33 per cent. in the total number of insane persons treated in institutions during the nine years ending 1889.

These few figures strikingly demonstrate how absolutely essential institution-treatment of the insane has become. They indicate that regular systematic treatment, under medical direction, and supervised by the State, is the chief means whereby a helpless class can receive adequate care.

What is true of the insane is equally true of the other defective classes, but the need, being less urgent, is only just becoming apparent.

Take the idiots, for example. From figures kindly furnished me by Dr. W. E. Fernald, Superintendent of the Massachusetts Asylum for Feeble-minded, I find there were in 1880, 76,895 idiots in the United States, only 2,429 of these being in institutions for idiots. During the last ten years, Dr. Fernald thinks the number of institutions for idiots has at least doubled.

We are at last waking up to the fact that idiots can be immensely improved by regular, systematic treatment in the institutions, under proper supervision on the part of the State.

Do not the same general arguments hold good in the care of epileptics as in the care of the insane and idiots? They represent a degenerate type of human being, prone to sink to a lower level if left uncared for; and, in sinking, they drag down others as well as themselves. They cannot be expected to improve any stock, but to act largely as a demoralizing influence on their environment. They are a weak link in the chain of evolution, and pretty certain to snap unless they can be relieved from the friction and strain of the sound links. Place them under favorable institution and supervisory treatment, and it is inevitable that marked amelioration in their condition will show itself, and

the community will be relieved of a menace to the vitality of the race, and a burden on its shoulders which it does not now know how to bear.

These are times when we are making a conscious or unconscious struggle, perhaps, to strengthen the race on its physical side; and one most important means of doing this, is to weed out the weak and degenerate. Place them by themselves where they will do the least harm and receive the most good, and leave the healthy individuals in the community to establish and perpetuate a stronger, sturdier, and better type of man.

Dr. Baker:—I only wish to say a word in conclusion. I am quite ready to admit all the criticisms Dr. Putnam has made. In my paper I made no claim, nor did I attempt to cover the whole field of epilepsy. I am too well acquainted with the different manifestations of epilepsy to advocate any such institution; especially of the semi-private kind which I have urged in my paper. I only maintain that a semi-private institution should be established for people of moderate means. I would make it purely voluntary.

The Chair then appointed as a committee to consider the matter brought up by the reader, Drs. T. W. Fisher, Morton Prince, Walter Channing, with Dr. Baker as one of the members of the committee.

Dr. Henry Fraser Campbell.

Dr. Henry Fraser Campbell died December 15, after an illness of some weeks. He was born in Savannah, Ga., February 10, 1824. His father, James Colgan Campbell, a native of County Antrim, Ireland, belonged to a family of the Presbyterian Scotch Irish Campbells. His mother, Mary R. (Eve) Campbell, a lady of fine intellectual endowments and high culture, was the only daughter of Joseph Eve, a name once familiar as connected with the early history of the cotton gin. This gentleman was the father of Professor Joseph A. Eve, of Augusta, and of Dr. Edward A. Eve, and the uncle of Prof. Paul E. Eve, of Nashville, who were the preceptors and trainers in medicine and surgery of Dr. Campbell in the earlier periods of his life. His education and moral culture, with that of his only brother, Dr. Robert Campbell, were carefully superintended by his mother, aided by his uncle, Dr. Robert Campbell. He began the study of medicine at the age of 15, and his career has been a most successful one. From a student he rose to high positions in the Medical Department of the University of Georgia. During the war he volunteered his services, and was afterwards commissioned regularly as a surgeon in the Confederate Army. After the war he was called to New Orleans, where he filled the chair of anatomy, and

later of surgery, in the New Orleans School of Medicine, but on account of ill health returned to Augusta. By his studies, lectures, and contributions to the literature of the profession, he has made his labors of great benefit to his profession and to mankind. Few medical writers in this country worked in so wide a field, or presented themselves with a personality recognizable in so many distinct departments, and he soon became familiar to the medical world, receiving honors from associations in Europe and the United States, having been elected President of the American Medical Association in 1885. He was the second Southern man to hold this position.

A MOTLEY LOT OF IMMIGRANTS.—The Report, to the State Board of Health, of inspection of immigrants at Port Huron to exclude dangerous diseases, during the first five days of December, shows the chances of the introduction of such diseases, because the immigrants passing through Michigan to States beyond are from so many different countries. The numbers and nationalities were as follows: Nine Arabs (from Jerusalem), seven Austrians, 1 Belgian, 36 Danes and Swedes, 2 Egyptians, 4 French, 15 French Canadians, 44 Germans, 4 German Jews, 4 Greeks, 23 Italians, 12 Irish, 5 Poles, 2 Portuguese, 6 Russians, 7 Russian Jews, 32 Scotch and English, 17 Scandinavians and 4 Swiss.

Their destinations were mainly "to Chicago and the Northwest;" but one was bound for the city of Mexico, so even that distant country might be interested in an inspection at Port Huron to isolate dangerous diseases. On four out of the five days, there was disinfection of baggage.

TO EMPTY A DISTENDED BLADDER.—To empty at once a distended bladder, is to expose the patient to the danger of a vesical hæmorrhage; it is necessary to desist as soon as the urine does not escape in a jet, but falls in dribblets, drop by drop.—*Med. Record.*

REMEDY FOR WARTS.—Consists in Fowler's solution, which given in weekly increasing doses, to adults two drops three times a day; to children, one-half drop three times a day.

LACTATION INDUCED BY MASSAGE.—A parturient patient of Dr. Mensinga (*Der Frauenarzt*, February, 1891) had never been able to suckle her children properly. On this occasion, the breasts were quite undeveloped; the practice of allowing the child to suck the dry nipples caused the mother great nervous irritation. Massage was practiced, the breasts steadily increased, and on the seventh day the child was suckled. Early in February the mother was still suckling her child, and both were doing well.—*N. Y. Med. Times.*

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, DECEMBER 26, 1891.

LOOKING BACK.

To take a retrospect of the past, adjust and balance accounts, is the common custom at this season of the year, and lest we appear singular, we will for the moment glance back over the work of THE JOURNAL during the past few months.

During the last half year there have been published in THE JOURNAL more than one thousand pages of reading matter, constituting a large volume, and containing one hundred and sixty-three contributions, in which is displayed the truly National character of THE JOURNAL, as may be observed in noting that thirty-three of the articles are from New York; twenty nine from Pennsylvania; twenty-two from Illinois; fourteen from Ohio, corresponding with the ratio in population of these four most populous of the States. Twenty-two other States, including Canada and England, are well represented by contributors. Thus fairly have the pages of THE JOURNAL reflected the labors and thought of the medical profession of this country.

That the showing is highly creditable, may go without saying. Our readers know that its character is a sufficient stimulant to inspire and bring out the very best work of the very best men in our American profession at the next meet-

ing. Already the officers of most of the Sections have their work well in hand, while their enthusiasm is of the acute, infectious type that is certain to spread, and attack hundreds of new men.

In this issue we publish the list of members and subscribers for THE JOURNAL. This requires eighteen pages, and the number of names enrolled is about six thousand, as against thirteen pages of names published last year.

Here again may be noted ample evidence of the truly National representation and character of the American Medical Association.

LOOKING FORWARD.

This marked increase of members of the Association indicates the attainment of a degree of momentum that is destined ere long to gather into the Association every reputable practitioner of medicine in this country.

At the next meeting in Detroit there will likely be an attendance of more than three thousand delegates, representing ten times that number of members of State and local societies, besides nearly the entire profession in and around Detroit. The estimate of three thousand delegates prospectively in attendance at the next meeting is not only reasonable, but it is quite low, as that number does not represent near one-half the delegate ratio strength of the American profession. One of the good things about these jottings is a knowledge of the fact that our friends in Detroit are making their preparations on an elaborate scale. More than four thousand can be entertained and cared for as gentlemen should be on such an occasion.

COMBINATIONS OF MEDICAL MEN.

Even the worm will turn against the heel that crushes it, and even medical men are beginning to demand some just recognition. The recent attempt in Arkansas by the medical men of a small community to protect themselves from imposition by notifying each other of the individuals who made unremunerative patients is an index of the feeling which is beginning to pervade the profession, and the action of the citizens of that community in organizing to boycott these physicians for doing that which every merchant does when he becomes a subscriber to a commercial agency, shows only too clearly how like slaves

the profession is regarded by a certain portion of the community.

Certainly it is true, that the profession as a whole is punctiliously mindful of the dictates of humanity. So true is this that a single slip in this direction by a physician, even if his action be within the bounds of strict right and justice, at once calls for loud complaints from the laity. The community has grown to judge us by altogether different standards from those which it employs in its judgment of others. When the physicians of Findlay, O., during an epidemic raised their fees from the modest sum of one dollar a visit to the still modest and inadequate sum of one dollar and a half a visit, the whole country was notified of their barbarity, by the inconsistent people of that town, who but a few short months before had flocked there for purposes of speculation, and who had held farms and "town" lots at enormous figures because they could, and who had not hesitated to receive such sums for their land as the "gas boom" brought on, and who took particular pains to close out their deals before the drop came. A recent attempt by the physicians of South Chicago, to form a protective association, led an attorney to announce the remarkable doctrine that physicians being licensed by the State, could not withhold their services when demand for them was made.

It is this same spirit which prevents the profession as a whole from exercising that influence in the community which its knowledge, training and culture should command. The animus which prevents legislation protecting physicians from unjust suits for alleged malpractice, is largely dependent upon this same condition of affairs.

DR. JOHN W. WATSON,¹ in his presidential address before the Northwest of Ireland Branch of the British Medical Association, recalls some very interesting facts. Within the past fifty years, the average duration of life has been increased ten years, largely due, directly and indirectly, to the labors of the medical profession. During this period, the advances in the medical sciences have been unusually great. The benefit of all these advances has been freely given to the people, without money and without price. These very advances in knowledge have thrown additional burdens and responsibilities on medi-

cal practitioners. The medical man of a half century ago was not called upon to make the refined diagnoses which modern science renders possible, and which modern ways demand. No thermometer, or microscope, or laryngoscope, speculum, or hæmometer, or sphygmograph, or any of many other instruments of exact research, demanded his consideration. Yet with all these the modern doctor must work. In making a diagnosis he must spend much more time with his patient than formerly, and to do him justice all around, he must spend much more time with his books and journals. Yet for all this increase of labor, and for the largely increased value of his visit, there is no increase in his remuneration in any way. In fact, there is an actual decrease.

Periodical literature gives evidence that movements are now on foot to secure for our profession the recognition due it.

It is idle to say that the profession receives its dues. Its methods are so out of harmony with the active commercial spirit of the age, that it cannot be understood. No better evidence of this is needed than the persistent misinterpretation of its motives by the daily press on matters relating to quackery. As to its *personnel*, it is actually and relatively superior to day, but does not receive the attention given the pompous doctor of "ye olden time."

To overcome the difficulties, it is necessary to secure the intelligent respect of the community. Increase of scientific knowledge cuts no figure in such a programme. Science is advancing by giant strides, but these strides can not be appreciated by those who can not understand them in detail. The means to secure respect, must be such as universally command respect to-day; and here we must take a lesson from our commercial brethren. An able financier has said that the keynote to modern success is "combination." The immense power of the great moneyed corporations is not due solely to their financial soundness, but partly also to the great number of individuals interested in them. The success of the great "trusts" proves the value of combination. The so-called "labor element" has found the value of combination.

In Great Britain and Ireland the physicians have combined in the great British Medical Association. The weekly issue of its journal now exceeds 17,500. This combination is not as well

¹ Provincial Medical Journal, Vol. x, p. 716.

organized as it should be, and will be in the future, nevertheless its influence is great, and its will, as expressed by its powerful journal, has during the past year secured at least two great reforms; the one was the frustration of the intention of the Government to abolish the class of factory surgeons, and the other was the practical and successful enforcement of the claims of the army surgeons to improvement in title, rank, and sick leave. It has now undertaken the redressal of the wrongs of the Irish dispensary doctors.

The American profession has in the American Medical Association an organization which can accomplish as much for them, if they will support it. But instead of a membership of 6000, it should have a membership of 60,000. With such a combination, the American profession would command respect, and carry conviction by its very weight. It is not to be supposed that such an organization would please everybody. Perhaps in its details it would please nobody. But in general its influence would be for the benefit of all, on broad lines.

Here is the opportunity before the profession. Will it take advantage of it?

LA GRIPPE.

This serious affection, that is at this time numbering its victims by the thousand, and proving fatal in many instances, has had a most singular career. Its first appearance in this country, two years ago, was heralded through the secular press with cheap wit and ridicule. All the same, its presence was made manifest in the aching bones, nervous prostration, painful muscles and distressed breathing of multitudes of people. A few succumbed to the first onset of the disease; others suffered from sequelæ which had a fatal termination, while a still greater number recovered very slowly, and others experienced a nervous prostration that will cling to them through life.

In the treatment of la grippe, the first most necessary thing is to require the patient to go to bed, and to there remain until convalescence is assuredly established. A nutritious diet of easy digestion, eggnog and red wines, strychnine, quinine and sedatives are indicated. Small doses of calomel and bicarbonate of soda rubbed

up with a little sugar of milk, to excite the glandular functions and keep the alimentary canal freely open, with rest of body and mind, is the course of treatment. We know of no specific remedy for this extremely serious but much ridiculed malady.

LABIAL CHANCER FROM AN UNUSUAL SOURCE.

—Dr. Moses Kleiner, of Denver, has reported the case of a servant maid who contracted a primary lesion, in consequence of applying vaseline to her chapped lips, which vaseline was taken from a pot or bottle belonging to a male boarder. The latter was the subject of a chancre of the penis and had been using the vaseline to anoint the part. The full account of the case may be found in the *Medical Record*, Sept. 12.

ARSENITE OF COPPER IN BOWEL TROUBLES.

—Dr. Z. P. Laudrum (*Med Summary*) speaks as follows in favor of this remedy: Our experience with the arsenite of copper has been both satisfactory and assuring. We have used it in more than sixty cases of bowel disorders during the last two years without its disappointing us in one single instance. We give it in suitable cases with more confidence than we give quinine for chills. It is especially valuable in the treatment of the summer complaints of children, in the chronic disorders of which the stomach is involved to the extent of almost constant nausea.

In every case of gonorrhœa warn your patient of the danger of conveying the disease to the eyes by the fingers, and of the fearful results of gonorrhœal ophthalmia.

SNEEZING favors the expulsion of the child in a case of labor, hence the use of tobacco, snuff or pepper, or other substances that will bring on the paroxysm by irritating the Schneiderian membrane, will hasten a tardy delivery.

NITRO-GLYCERIN FOR ASPHYXIA.—In a case of asphyxia from the inhalation of illuminating gas, Hoffmann (*Allgem. Med. Ztg.*) succeeded in relieving the symptoms by the subcutaneous administration of nitro-glycerin in doses of a hundredth of a grain. The injection was made in the precordial region, and was followed by marvelously prompt results.

AN EPIDEMIC OF TUBERCULOSIS.—An epidemic of tuberculosis has broken out in the electrical workshops at Paris. Out of thirty-five workmen thirty-two are consumptive. Twenty-three have become so since entering the workshops.

FOR cold in the head, there is no better remedy than gelsemium. One good, large dose, say ten minims of the fluid extract, taken upon going to bed, will effectually dispose of this troublesome and uncomfortable affection. One dose is usually sufficient.—*Med. Summary.*

A NUMBER of cases of chorea have been reported as cured by the use of iodide of potassium. It is undoubtedly that class of cases in which there is a blood discrasia. One grain in solution is given three or four times a day to a child.

POULET, in the treatment of epilepsy advises tincture of Calabar bean with bromide of potassium. In five obstinate cases which were treated with bromide of potassium without results, a cure was accomplished with the addition of Calabar bean.

SCHLEICH advises the internal use of the iodide of potassium to assist in the granulation of deep wounds. The wounds quickly assume a more healthy appearance. The granulations increase rapidly, and the period of healing is greatly shortened.

If pulverized ipecac in water be applied freely to a surface poisoned by rhus, the pain, itching and heat will be immediately relieved, and a cure quickly follows.

TO ARREST the secretion of milk the external application of one part of camphor in six parts of oil of turpentine is often of great service.—*Medical Record.*

STRYCHNINE FOR DRUNKENNESS.—In consequence of the remarkable success claimed in the treatment of drunkenness with hypodermic injections of strychnine, this method of treatment was tried in the city hospital in Görlitz, Silesia, but the results were almost entirely negative.—*Boston Medical Journal.*

BOOK REVIEWS.

A PRACTICAL TREATISE ON THE DISEASES OF WOMEN. By T. GAILLARD THOMAS, M.D., LL.D., emeritus professor of diseases of women in the College of Physicians and Surgeons, New York, and PAUL F. MUNDÉ, M.D., professor of gynecology in the New York Polyclinic. New (sixth) edition, thoroughly revised and rewritten by Dr. Mundé. In one large and handsome octavo volume of 824 pages, with 347 illustrations. Cloth, \$5.00; leather, \$6.00. Philadelphia: Lea Brothers & Co., publishers. 1891.

This truly great work, so well known to every gynecologist, has long since passed beyond the domain of criticism by THE JOURNAL reviewer. This new edition comes to us fresh from the hands of its talented authors, bearing on its pages the well-known presentations of former editions, to which have been added a sound judgment happily expressed of the new work in this field during the last few years. The work of revision

being done by Dr. Mundé. In fact, he has done his work so well that his name properly appears as joint author. The list of illustrations has been greatly increased in number, and enriched by a beautiful series of accurate drawings, photographically reproduced. The book is destined in its new form to maintain its position, and nothing more effective could be said in its praise.

REVIEW OF ESSENTIALS OF NERVOUS DISEASES AND INSANITY. By JOHN C. SHAW, M.D. Published by W. B. Saunders, Philadelphia.

This little quiz compend is spottedly good, fair and defective, and as a compend is certainly not compendious, for very many nervous and mental diseases are omitted, and seldom encountered disorders, such as Morvan's disease, are included.

The classification of insanity is decidedly wrong. For instance, senile dementia he places under the head of a simple insanity not connected with degenerative neuropathic states, and then proceeds to say: "It is the result of physical changes in the brain, atheroma, endarteritis and periarteritis; general disturbances in nutrition, localized atrophies, together with the changes in the other organs found in senility."

In respect to such nervous diseases as the author has had experience with, his descriptions are very good.

EPIDEMIC INFLUENZA; Notes on its Origin and Method of Spread. By RICHARD SISLEY, M.D. London: Longmans, Green & Co. For sale by A. C. McClurg & Co., Chicago. Price, \$2.50.

This monograph is timely in its appearance, as there is a very general prevalence of the disease in many parts of our country, and particularly in the more populous centres.

The author gives a very satisfactory nomenclature of influenza, its definition, the origin, and spread of the disease by contagion, with a history of the several epidemics which have prevailed.

A TEXT BOOK ON PRACTICAL THERAPEUTICS, with especial reference to the application of remedial measures to disease. By HOBART AMORY HARE, M.D. Second edition. Enlarged and thoroughly revised.

We are much gratified at the receipt of this new edition of Dr. Hare's work on Therapeutics. While there was very much in the first edition deserving of criticism, showing as it did a degree of undue haste in preparation, the author has been at pains to eliminate many imperfections and now presents the medical profession with a work that is deserving of commendation. The latest knowledge pertaining to new remedies is introduced, including the method of employing the rest cure, and the use of suspension in the treatment of locomotor ataxia and kindred affections.

THE PHYSICIAN'S VISITING LIST, Lindsay & Blakiston.

This is a long time favorite with many thousand physicians.

VISITING LIST, Chambers & Co.

Very convenient and well arranged.

NECROLOGY.

WASHINGTON F. PECK, A.M., M.D., of Davenport, Ia., died December 12, 1891, in his fifty-first year. He was a native of Galen, N. Y., and a graduate of Bellevue Hospital Medical College. He was *interne* at Charity and Bellevue for eighteen months, and at Lincoln Hospital, Washington, for a year, before settling permanently for practice at Davenport. He was chosen President of the State Medical Society in 1876, professor of surgery in the medical department of Iowa State University, and Dean of Faculty from 1869. He was surgeon-in-chief of the Rock Island Railroad from 1875, surgeon to Mercy Hospital, Davenport, and consulting surgeon to the Mercy Hospital, Iowa City. He was chairman of the Surgical Section of the American Medical Association in 1883, and delegate therefrom to two International Congresses. He was surgeon of the Iowa Soldiers' Orphan Home, and prominent in other local charities and in life insurance matters. He was a man of originally strong physique, much endurance, a strength of purpose and reliance that seemed to destine him to a long and meritorious leadership in every professional and social department which obtained his interest and attention.

SURGEON M. L. RUTH, of the Navy, died at Brooklyn on the 13th inst., in his forty-seventh year. He was one of the best known of the naval staff, especially from his being the means of saving the life of the present Secretary of the Navy, when the home of the latter was destroyed by fire and two members of his family lost their lives. The impairment of Dr. Ruth's health during a year past, led him about three months ago to resort for treatment to the Naval Hospital at Brooklyn, and he there succumbed to complications of cardiac and renal disease.

SELECTIONS.

FETID FEET.—The cause of this unpleasant ailment is to be found in the unnatural custom of wearing shoes. Nature contemplated a shoeless animal when she made man, and she so arranged the epithelium on the soles of his feet as to provide for a rapid reproduction of the layers worn off in walking. So well suited to man's necessities was this arrangement, that Parkes, after discussing the merits of various foot-gear, concludes that the best shoe for soldiers is no shoe at all. But man had to improve on nature, and the way he has done it is by encasing the foot in an impermeable casing of tanned leather. This prevents the removal of the epithelium from the sole, and also prevents the escape of perspiration, which, keeping the dead epithelium moist, infallibly renders it odorous.

The reason why washing does not relieve this is, that soap and water alone are insufficient to remove the epithelium. No amount of rubbing will do this; and it is doubtful if anything short of a vigorously wielded

scrubbing brush will do so. But the Greeks had something better even than this. Some of our readers will remember the description given by Xenophon of the games instituted by Cyrus, before his march to the field of Cunaxa, and that among the prizes given to the victors were "golden-flesh scrapers." Not even a brush equals in efficiency the scraping with some metallic instrument, like a dull paper-cutter.

We would recommend, therefore, for fetid feet, that the sufferer should soak the feet in hot water, and scrape them well, every night, until the nuisance is abated; and to keep this up weekly thereafter, with morning ablutions of cold water with no soap, but followed by vigorous rubbing with a course towel. This is better than all the salicylated powders or ointment.—*Times and Register*.

SLEEP is "nature's balmy restorer." The old saw, "six hours for the wise and eight for children and fools," is nonsense. During growth, proper physical development, especially of the brain, demands plenty of sleep; and the more nervous or precocious the child, the more sleep should be the rule. If not, we may expect premature death, or an early and too intellectual growth. Until the fifteenth year is reached, there should be ten hours' sleep; from 15 to 20, nine hours, and after maturity, while each may judge for himself, eight hours is a good rule. Plenty of refreshing sleep will prevent more nervous derangements than medicine will cure.—*Kansas Med. Journal*.

MISCELLANY.

AT THE meeting of the American Medical Association in 1892, the work of the Section on State Medicine will be arranged as follows:

The first day will be given to the address of the chairman and the report of the committee on "School Hygiene." As this committee will make its final report, the entire session, after the chairman's address and the necessary routine business, will be devoted to its discussion.

The second day will be devoted to the discussion of the "Pollution of Rivers and Inland Streams, its effect upon Public Health, and Measures for its Prevention." An effort will be made to have this subject handled from every possible point of view. Members of the Association who have given study to the subject will kindly prepare papers, and notify the Secretary of the titles of these papers.

The third day will be given to miscellaneous papers. Members desiring to read papers on this day will kindly send in titles. Respectfully,

LAWRENCE F. FLICK,

Sec'y of Section on State Medicine.

736 Pine St., Philadelphia.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from December 12, 1891, to December 18, 1891.

By direction of the Acting Secretary of War, a board of medical officers, to consist of Col. Bernard J. D. Irwin, Surgeon; Lieut.-Col. Charles H. Alden, Surgeon; Major Alfred C. Girard, Surgeon; First Lieut. Alfred E. Bradley, Asst. Surgeon, is constituted, to meet at Hdqrs. Dept. of the Missouri, Chicago, Ill., on the 1st day of February, 1892, for the examination of candidates for admission to the Medical Corps of the Army, and for such other business as the Surgeon-General may desire to bring before it.

Capt. Edgar A. Mearns, Asst. Surgeon, so much of par. 1, S. O. 265, A. G. O., as directs him to report to the commanding officer, Ft. Mackinac, Mich., is revoked; he will proceed to El Paso, Tex., and on arrival there, report for duty to Lieut.-Col. John W. Barlow, Corps of Engineers, member of the commission appointed for the location and marking of the boundary between Mexico and the United States. By direction of the Acting Secretary of War.

First Lieut. Philip G. Wales, Asst. Surgeon U. S. A., granted leave of absence for one month with permission to apply for an extension of one month.
